In his preface he tells us that he has endeavoured to give a comprehensive account of the Anatomy of Man studied from the Morphological standpoint. Accordingly, we find that, after a few explanatory paragraphs on the meaning of terms used in description, he proceeds to state his conception of a Cell. His definition is so comprehensive that he regards it in its simplest form as a minute speck of protoplasm without either nucleus or cell-wall; and, in this respect, he may be said to coincide with the view held by Stricker in his well-known article on the Cell. He then briefly describes the process of Karyokinesis, and very properly states that the study of the specialization of the products of cell multiplication is the only trustworthy guide to the solution of the many morphological problems which Human Anatomy presents. This very naturally leads to an account of the Development of the Embryo, which is, however, compressed into so few pages that we doubt whether a beginner can derive from it a clear conception of the very elaborate set of changes which lead from the simple laminated blastoderm to the form of the fœtus at the time of birth.

A chapter on Histology or tissue-anatomy comes next in order. He groups the tissues into five classes—epithelial or surface limiting; connective or skeletal; nervous or sensory; muscular or contractile; blood and lymph or nutritive. This classification is both simple and convenient, and is much to be preferred to the grouping into cellular, fibrous, membranous and tubular tissues, sometimes adopted. In the course of this chapter he in part fills up some of the gaps in the section on embryology, by describing the development of the nervous and vascular systems.

The skeleton is next described, and following the plan pursued by Prof. Humphry in his well-known treatise, and by Hyrtl, Gegenbaur, Krause, and others in their systematic works, he describes the joints and ligaments along with the bones with which they are associated. This arrangement, undoubtedly, has certain advantages more especially in the direction of economizing space in description.

About one-third of the work, extending to 248 pages, is occupied with the chapters to which we have just referred, and the remaining two-thirds is devoted to an account of the soft parts, including the anatomy of the brain and organs of sense. In this, the larger division of his text-book, Prof. Macalister alters his mode of treating the subject, and departs from the method which systematic writers are in the habit of pursuing.

The rule, almost without exception, has been to describe in separate chapters the muscular, vascular, nervous, alimentary, respiratory, and genito-urinary systems, so as to bring before the student in a continuous series all those organs which possess corresponding properties. To some extent, therefore, the arrangement adopted in our text-books of systematic anatomy has had a physiological basis.

Dr. Macalister has not followed this plan. He has adopted an arrangement on a topographical basis, *i.e.* according to the method pursued in the dissecting-room, in which the student works out for himself the constituent parts of the body as he displays them in the course of his dissections. This method of studying the anatomy of the human body is, as everyone will admit, of enormous importance—indeed, we may say of primary value—to the practitioner of medicine and surgery. But it is the custom of the schools to distinguish between the analytical or dissecting-room method, in which the body is picked to pieces by the dissector himself, and the synthetical or systematic method, in which the body is, as it were, built up by the teacher for the student. This custom is the fruit of long experience, for whilst giving full value to the topographical or regional aspect of anatomy, it enables the teacher to show to the student the continuousness of such systems as the vascular, nervous, and alimentary, and to point out their physiological relations. For it should be kept in mind that anatomy is the basis of physiology, as well

as the foundation of that side of medical and surgical practice which is based on a sound knowledge of regional anatomy. The incomplete recognition of the physiological aspect of anatomy is, we think, the weak part of the book, and it is especially shown in the scanty notice which is taken of the action of the muscles and their association with the movements of the joints.

To enable both these lines of anatomical study to be pursued, the student is accustomed to employ at least two text-books; the one in connection with his systematic work, the other as a guide to the dissection of the body. Prof. Macalister apparently expects, as, indeed, he states in his preface, that his text-book should stand in the place of the two customarily employed. We doubt, however, whether this expectation will be fulfilled. For his text-book, in addition to what is essential in topographical description, by containing an account of the microscopic structure of tissues and organs, a section on embryology, and a detailed description of the bones, is necessarily a work of considerable size and weight, and too cumbersome to be conveniently carried to and fro by the student, as is required with a dissecting-room manual. On the whole, therefore, we prefer the old and well-accustomed lines on which text-books have for so long been written, to Prof. Macalister's modified plan.

But whilst expressing our inability to regard the method which has been followed in the descriptive anatomy of the soft parts as an improvement on the customary arrangement of systematic text-books, we recognize with pleasure the clearness of the descriptions and the many suggestive hints, both morphological and practical, which the book contains. The volume is profusely illustrated with upwards of eight hundred wood-cuts, about one half of which are original figures.

OUR BOOK SHELF.

A Treatise on Ordinary and Partial Differential Equations. By W. W. Johnson. (London: Macmillan, 1889.)

WE have read Prof. Woolsey Johnson's work with some interest: his style is clear, and the worked-out examples well adapted to elucidate the points the writer wishes to bring out. He appears to recognize Boole, but, so far as the text is concerned, does not acknowledge the existence of Mr. Forsyth's fine work. We do not say that he was under any obligation to do so, but nowadays we are so accustomed to see a list of authors upon whom a writer has drawn that we missed it here. "An amount of space somewhat greater than usual has been devoted to the geometrical illustrations which arise when the variables are regarded as the rectangular co-ordinates of a point. This has been done in the belief that the conceptions peculiar to the subject are more readily grasped when embodied in their geometric representations. In this connection the subject of singular solutions of ordinary differential equations, and the conception of the characteristic in partial differential equations may be particularly mentioned." This is certainly the most prominent feature of the early chapters, and it is, to our mind, clearly put before the student. Reference is duly made to Prof. Cayley's work in the *Messenger of Mathematics* (vol. ii.), which initiated the present mode of treatment of the subject, but not to Dr. Glaisher's "Illustrative Examples" (vol. xii.), nor to Prof. M. J. M. Hill's paper (London Math. Soc. Proc., vol. xix.), in which the theorems *stated* by Prof. Cayley are proved. This paper, though read before the Society, June 14, 1888, may not have reached the author before his work was in the printer's hands: we do not say that a perusal of it would have called for any further notice than a reference. Symbolic methods come in for their due meed of recognition and employment. The author satisfies himself with referring the student to the table of contents for the topics included and the order pursued in treating them. The work consists of twelve chapters divided up into twenty-four sections: i. (1) discusses the nature and meaning of a differential equation between two variables; ii. (2, 3, 4,) equations of the first order and degree; iii. equations of the first order, but not of the first degree, (5) singular solutions (discriminant, cusp-, tac-, and node-loci), (6) Clairaut's equation, (7) geometrical applications, orthogonal trajectories; iv. (8) equations of the second order; v. (9, 10) linear equations with constant coefficients, in (10) symbolic methods are employed; vi. (11–13) linear equations with variable coefficients; vii. (14, 15) solutions in series; viii. (16) the hypergeometric series; ix. (17) special forms of differential equations, as Riccati's equation (due reference is made to Dr. Glaisher's classical paper in the Phil. Trans. for 1881), Bessel's equation, and Legendre's equation (reference is made to text-books and memoirs); x. (18–20) equations involving more than two variables; xi. (21, 22) partial differential equations of the first order; xii. (23, 24) partial differential equations of higher order. Examples for practice are added at the end of each section. Though Prof. Johnson cannot lay claim to have made here any additions to our knowledge of the subject, he has produced an excellent introductory hand-book for students, and this, we expect, was the object he proposed to himself in its compilation. We have omitted to state that all use of the complex variable is eschewed.

The Land of an African Sultan: Travels in Morocco 1887, 1888, *and* 1889. By Walter B. Harris, F.R.G.S. (London: Sampson Low and Co., 1889.)

A GOOD deal has been written about Morocco lately, and Mr. Harris's volume is an interesting, although not a very important, contribution to the literature of the subject. He describes first a journey through northern Morocco, then a journey with H.B.M. Special Mission to the court of the Sultan at Morocco city, next a visit to Wazan and a ride to Sheshuan; and in a final chapter he sums up the impressions produced upon him by the Moors and their country. In the chapter on his ride to Sheshuan, he describes a place which had been "only once before looked upon by Christian eyes." Mr. Harris does not pretend to have produced an exhaustive work on Morocco; but he presents clearly what he himself has had opportunities of observing.

Wayside Sketches. By F. Edward Hulme, F.L.S., F.S.A. (London: Society for Promoting Christian Knowledge, 1889.)

THIS is a pleasantly conversational book on all sorts of subjects more or less connected with natural history or country life: birds, caterpillars, flowers, snow-crystals, and the forms of clouds, all come in for a share of attention. Without having any scientific pretensions of its own, the book may well serve to rouse a first interest in many branches of science. The numerous illustrations are very good indeed.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Influenza.

THE following paragraph, taken from Sir David Brewster's "Life of Sir Isaac Newton," is not uninteresting at the present time:—

"Some light has been recently thrown on the illness of Newton by Dr. Dowson, of Whitby, who, at a meeting of the Philosophical Society there on the 3rd of January, 1856, read a paper 'On the Supposed Insanity of Sir Isaac Newton,' in which he has shown that the malady with which he was afflicted in September 1693 was probably influenza or epidemic catarrhal fever, which prevailed in England, Ireland, France, Holland, and Flanders in the four last months of 1693. This distemper, which lasted from eight or ten days to a month, was so general, that 'few or none escaped from it'; and it is therefore probable, as Dr. Dowson believes, that Newton's mental disorder was merely the delirium which frequently accompanies a severe attack of influenza. See Dr. Theophilus Thomson's 'Annals of Influenza or Epidemic Catarrh in Great Britain,' published in 1852 by the Sydenham Society. See also the Philosophical Transactions for 1694, vol. xviii. pp. 105-115." W. GREATHEED.

ABOUT forty-five years ago I paid a visit with a friend to the laboratory of the celebrated chemist Prof. Schonbein, the discoverer of ozone in the atmosphere and the cause of influenza. Just prior to our visit the Professor had obtained some ozone, and had inhaled it for the purpose, as he said, of giving himself influenza, in order to ascertain how it would affect him. We both distinctly observed most of the ordinary symptoms of the malady. AUGUSTUS HARVEY.

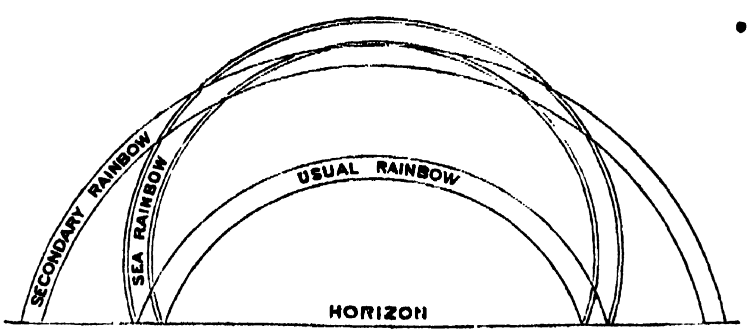
Rainbow due to Sunlight reflected from the Sea.

I HAVE never heard of a rainbow, due to the image of the sun in water, having been seen; and I think the following letter, from an old student of mine of sixteen years ago, may interest your readers. WILLIAM THOMSON.

The University, Glasgow, January 7.

ON September 18, 1889, I saw a rainbow, caused, not by the direct rays of the sun, but by their reflection from the sea.

We were at the height of 900 feet; the sky was all clouded except along the western horizon; the sun, an hour before setting, was hidden; but its rays were reflected from the sea. A drizzle was falling, and my companion was remarking how strong the light from the sea was, when it occurred to me that it might give a bow. And there it was behind us—not the usual recumbent bow, less than a semicircle, but an overhanging one, greater than a semicircle. The clouds were drifting from the west, so that the sun came into view; and the usual rainbow became visible with its secondary bow; *so that three rainbows were seen at once.* The sea-bow and the usual bow were identical at the horizon. The angle between them was greater than the sun's



angular height, but not double. It seemed as if the complementary segment of the rim had been folded up from beneath into view, but that the colours were not reversed. The sea-bow was just as bright as the secondary bow, which it intersected.

From the fact that the three were seen together, for over 3 minutes, at least in part, I would argue that it is no unusual sight, and that in Scotland, where bows are so frequent, and plenty of comparatively smooth water available, this sea-bow may be looked for and seen.

I may mention, also, that I saw a fourth bow that evening. After the sun had set, a bow of one colour, an orange-pink, took the place of the usual bow. The source of light, I thought, was a cloud just over the place where the sun had set.

WILLIAM SCOULLER.

86 Calle de la Independencia, Valparaiso, November 9, 1889.

Osteolepidæ.

YOUR reviewer R. L. is mistaken in condemning so absolutely the above form. The word "Osteolepus" would be a legitimate adjective expressing the same idea as the substantive Osteolepis; and the patronymic of the "Osteolepi" would be simply "Osteolepidæ," and not "Osteolepididæ."

It may be useful for R. L. and some others to apprehend this principle in word-building—viz. that compound Greek adjectives do *not* take the lengthened genitive as root; thus the correct Latin equivalent for the corresponding Greek adjective is *not* "echinodermatus" but "echinodermus," not "distomatus" but "distomus." Hence, the correct form for the neuter plural of the former is "Echinoderma;" and for the neuter singular of the latter is Distomum. And it would be wrong to write "Distomatidæ" as the family name, and correct to write "Distomidæ." Hence Osteolepidæ and the like are admissible, since they may be considered as formed from adjectives, and not from the substantive (of questionable form itself) in -is.

Exact Thermometry.

SINCE the publication of my letter in NATURE (December 19, 1889, p. 152) on the cause of the rise of the zero-point of a thermometer when exposed for a considerable time to a high temperature, two letters on the same subject have appeared, one from Mr. Herbert Tomlinson (January 2, p. 198), the other from Prof. E. J. Mills (January 9, p. 227), who replies to my objections to the plastic theory.

Mr. Tomlinson considers that my experiments seem to leave no doubt that compression, due to the plasticity of the glass, is not the main cause of the rise of the zero-point, but he considers that it is not merely the prolonged heating, but also the change of temperature (heating or cooling), that is effective in bringing about the change. I have not yet had time to make any special experiments to test this point, but I may perhaps mention that such data as I possess seem rather to point to the conclusion that long-continued steady heating is more effective than alternate heating or cooling. As the following experiment, made about a year ago, seems to bear on the point, I give the results:—

									Total rise of zero
Approximate time in hours.	6	3	6	6	6	31	6	6	
Rise of zero-point	1°·6	0°·15	0°·85	0°·5	0°·1	1°·2	0°	0°	4°·4

Two other thermometers, heated each day for about six hours, showed after nine days rises of zero-point of 3°·8 and 4°·1 respectively, but in these cases the change was apparently not quite complete. The temperature was in each case 280°, and all these thermometers belonged to the same batch as those employed in my experiments already described in NATURE.

Prof. Mills does not regard the experiments as conclusive, but criticizes my results in the following words: "The zero movement, however, only ranged from 1° to 1°·2—small readings which might very possibly have been obtained, or not, on either of the thermometers at other times." This criticism, in striking contrast to the rest of the letter, appears to be rather unkind either to me or to my thermometers, I hardly know which. I sincerely hope that none of my thermometers are capable of such erratic behaviour as to show changes of zero-point of 1° (or even twice this amount if the plastic theory is correct) without extraordinary treatment, or that my readings of temperature are reliable only to within 1° or so. But to make the matter more certain, I will continue the heating of the two thermometers, A and C, under the same conditions as before, and will also heat two more thermometers under similar conditions to about 360°.

Prof. Mills mentions the very curious behaviour of lead-glass thermometers at different temperatures, but his objection on that score to the temperature 280° does not seem to apply, as my thermometers are all made of soft German soda-glass. It may, however, be useful to heat two more thermometers to a temperature of about 220° in order to compare the total rise with that at 280° and 360°.

With regard to the statement that the final state of a thermometer kept at the ordinary temperature for an infinite time would differ from that of the same thermometer after being subjected to prolonged heating at a high temperature, I am not prepared to give a decided opinion either one way or the other, but it does appear to me to be rather a daring procedure to make observations of the minute changes of zero-point over a few years, and to extrapolate from a decade or so to eternity.

I am also quite willing to admit that there may be other causes tending to raise the zero-point besides the equalization of tension, such, for instance, as the chemical changes alluded to by Prof. Mills; but I should like to ask, as I am ignorant on the point, whether there is any experimental evidence of their nature or existence. SYDNEY YOUNG.

University College, Bristol, January 11.

Foreign Substances attached to Crabs.

IN your issue of December 26, and also in exhibiting his collection of crabs before the Linnean Society, Mr. Pascoe cast some doubt on the function of the two pairs of modified legs of *Dromia vulgaris*, which are usually supposed to be adapted to the retention of the sponge with which it covers its carapace.

That these legs were really used for this purpose I was enabled to observe, during my stay at the zoological station in Naples last winter. I had in my tank several specimens, in some of which the sponge had also extended on to the ventral surface, over the edge of the carapace, thus securing a firm hold apart from the action of the legs. In all specimens, however, there are seen, when the sponge is removed, which requires considerable force, two oblique depressions into which the legs fit, giving them thus a distinct hold on the sponge.

If the latter be, however, removed from the animal but left in the tank, the crab soon sets to work to regain possession of its covering, and can be seen to use its modified hinder pairs of legs most effectually for this purpose. It would seem therefore beyond doubt that these modified legs serve not only for holding on the sponge, but also for getting hold of a new sponge, should the old one get injured or die, as must happen not unfrequently.

F. ERNEST WEISS.

The Zoological Laboratory, University College, January 6.

Galls.

I AM sorry if I unintentionally misrepresented the opinions of Prof. Romanes and Dr. St. George Mivart in suggesting that they wished to assail the theory of natural selection in their recent communications to NATURE on this subject. They must, however, pardon me for saying that I still think the extract to which I alluded in my note admits this interpretation. As my views of the relations of gall-formation to the theory of natural selection are clearly at variance with those of your correspondents, perhaps you will allow me space to give briefly the grounds upon which I base my conclusions.

There are in England about ninety well-known varieties of galls, and of this number fully a third are found in the oak. About half the oak-galls are formed on growing leaves. In nearly one-third of the total number the grub is hatched, and the gall is fashioned in a developing bud. We can readily imagine, in the case of a tree with deciduous leaves, that the presence of a few galls upon its foliage would not greatly affect its chances of survival, if its fitness was in other respects complete. It is otherwise when a gall occupies the position of a developing bud, especially when the bud is a terminal one. In this case there occurs coincidently with, and as a result probably of, the adventitious formation, an arrest of normal development and growth. Indeed, I believe "the gnarled and twisted oak" owes many of its gnarls and most of the twists to the common oak-apple and other bud-galls. If a tree endowed with less developmental vigour and with fewer supplementary buds than the oak had been exposed to the repeated attacks of the insects for many generations in a struggle for existence, it would doubtless have long ago succumbed, and it would have done so by a process of natural selection operating in the ordinary manner, and not "at the end of a long lever of the wrong kind," whatever that may mean. This selective process in the case of gall-bearing trees has left possible traces of its action to-day, for I am unaware that any other English tree than the oak is attacked by terminal bud-galls. The terminal leaf-galls of certain Salices and Conifers can scarcely affect their growth and development to the same extent as the bud-galls.

When we compare pathological tumours in the higher animals with these vegetable excrescences, we must make due allowances for the different conditions under which each lives. I cannot then see that the "morphological specialization" of galls, which, for the most part, are composed of hypertrophied reproduction of the simpler vegetable tissues, is greater than that exhibited by man himself, when, for instance, he becomes the involuntary host of Dr. Lewis's *Filariæ*, and his leg the seat of *Elephantiasis lymphangiectodes*, accompanied by hypertrophy of many integumentary structures of the limb. Oak-spangles, on the other hand, are to my mind comparable to the circular nests of ringworm, or to the sprouting epithelium of a *Verruca necrogenetica*. Such comparisons may be of little scientific value, yet I take it they are as useful in their place as attempts to gauge the amount of "disinterestedness" shown by a cabbage when it becomes the unwilling host of the gall-producing *Ceuthorhynchus sulcicollis*. W. AINSLIE HOLLIS.

Brighton, December 30, 1889.

The Evolution of Sex.

THE interesting note of Mr. M. S. Pembrey in your issue of January 2 (p. 199), induces me to draw the attention of your correspondent to a short paper of mine just published (or in course of publication) in the *Ibis*, where I communicated the experiences of a friend, who had hatched a series of parrot eggs, belonging to the genus *Eclectus*, in which the young males are green, the young females red. It is remarkable that by far the larger number of the birds hatched were males. In each case only two eggs were laid, and the breeder himself, without being able to tell why, is of opinion that nearly all his hatches consisted of male birds. As there are still many embryos of those *Eclectus* in my hands, the sex of which is not yet determined, I hope to be able to make known the result of my investigation later, whether the pairs are always males, or always females, or consist of a male and a female bird, at least sometimes. Meanwhile, I should be glad to hear if anything more is known about the sexes of birds which lay only two eggs at a time.

A. B. MEYER.

Royal Zoological Museum, Dresden, January 5.

"Manures and their Uses."

ALLOW me to thank the well-known writer "W." for his review of the above-mentioned book. "W." does not hold with the view that "farmyard manure is erroneously supposed to contain *all* the necessary plant-foods required for the growth of plants." I believe, with M. Ville and others, that "the farmer who uses nothing but farmyard manure exhausts his land." "W." speaks of this as an "obvious fallacy." If the statement is wrong, would "W." kindly answer the quotation given on p. 76 of the book in question. The quotation "runs" as follows:—

"M. Grandeau (the French agricultural authority) recently estimated that one year's crop in France represents 298,200 tons of phosphoric acid, of which only 151,200 tons were recovered from the stable dung, thus leaving a deficit of 147,000 tons, equal to over one million tons of superphosphate, to be made good by other means.

"M. Grandeau also estimated that the entire number of farm animals in France in 1882, representing a live weight of 6,240,430 tons, had accumulated from their food 193,453 tons of mineral matter containing 76,820 tons of phosphoric acid. These figures give some idea of the enormous quantities of phosphoric acid required to restore to the soil what is continually being carried away by the crops sold off the farm."

It must be borne in mind that in the above estimates, M. Grandeau includes the purchase of oil-cakes and other feeding stuffs. Therefore, if farmyard manure only contains about half the amount of phosphoric acid (to say nothing of nitrogen, potash, &c.) required to retain the land in a fertile condition, how can I have attached "too much prominence to chemical manures, and too little importance to stock-feeding as a manurial agency"? A. B. GRIFFITHS.

[DR. GRIFFITHS assumes that because, as asserted by M. Grandeau, the balance of fertilizing matter in France is against the land, "the farmer who uses nothing but farmyard manure exhausts his land." This is arguing from general principles to special cases, and there is no sequence in his reasoning. A nation may be rushing to ruin, but that does not prevent an individual from growing rich. Phosphates and nitrates may be diminishing, but that does not prevent them from accumulating on any particular farm. We traverse Dr. Griffiths's statement without qualification, that the farmer who uses nothing else but farmyard manure exhausts his land. We believe he improves his land.—THE REVIEWER.]

MAGNETISM.[1]

II.

WHEN one considers that the magnetic property is peculiar to three substances—that it is easily destroyed by the admixture of some foreign body, as manganese—one would naturally expect that its existence would depend also on the temperature of the body. This is found to be the case. It has long been known that iron remains magnetic to a red heat, and that then it somewhat suddenly ceases to be magnetic, and remains at a higher temperature non-magnetic. It has long been known that the same thing happens with cobalt, the temperature of change, however, being higher; and with nickel, the temperature being lower. The magnetic characteristics of iron at a high temperature are interesting. Let us return to our ring, and let us suppose that the coils are insulated with a refractory material, such as asbestos paper, and that the ring is made of the best soft iron. We are now in a position to heat the ring to a high temperature, and to experiment upon it at high temperatures in exactly the same way as before. The temperature can be approximately determined by the resistance of one of the copper coils. Suppose, first, that the current in the primary circuit which we use for magnetizing the ring is small; that from time to time, as the ring is heated and the temperature rises, an experiment is made by reversing the current in the primary circuit, and observing the deflection of the galvanometer needle. At the ordinary temperature of the air the deflection is comparatively small; as the temperature increases the deflection also increases, but slowly at first; when the temperature, however, reaches something like 600° C., the galvanometer deflection begins very rapidly to increase, until, with a temperature of 770° C., it attains a value of no less than 11,000 times as great as the deflection would be if the ring had been made of glass or copper, and the same exciting current had been used. Of course, a direct comparison of 11,000 to 1 cannot be made: to make it, we must introduce resistance into the secondary circuit when the iron is used; and we must, in fact, make use of larger currents when copper is used. However, the ratio of the induction in the case of iron to that in the case of copper, at 770° C., for small forces is no less than 11,000 to 1. Now mark what happens. The temperature rises another 15° C.: the deflection of the needle suddenly drops to a value which we must regard as infinitesimal in comparison to that which it had at a temperature of 770° C.; in fact, at the higher temperature of 785° C. the deflection of the galvanometer with iron is to that with copper in a ratio not exceeding that of 1·14 to 1. Here, then, we have a most remarkable fact: at a temperature of 770° C. the magnetization of iron 11,000 times as great as that of a non-magnetic substance; at a temperature of 785° C. iron practically non-magnetic. These changes are shown in Fig. 8. Suppose now that the current in the primary circuit which serves to magnetize the iron had been great instead of very small. In this case we find a very different order of phenomena. As the temperature rises, the deflection on the galvanometer diminishes very slowly till a high temperature is attained; then the rate of decrease is accelerated until, as the temperature at which the sudden change occurred for small forces is reached, the rate of diminution becomes very rapid indeed, until, finally, the magnetism of the iron disappears at the same time as for small forces. Instead of following the magnetization with constant forces for varying temperatures, we may trace the curve of magnetization for varying forces with any temperature we please. Such curves are given in Diagrams 9 and 10. In the one diagram, for the purpose of bringing out different points in the curve, the scale of abscissæ is 20 times as great as in the other. You will observe that the effect of rise of temperature is to diminish the maximum magnetization of which the body is capable, slowly at

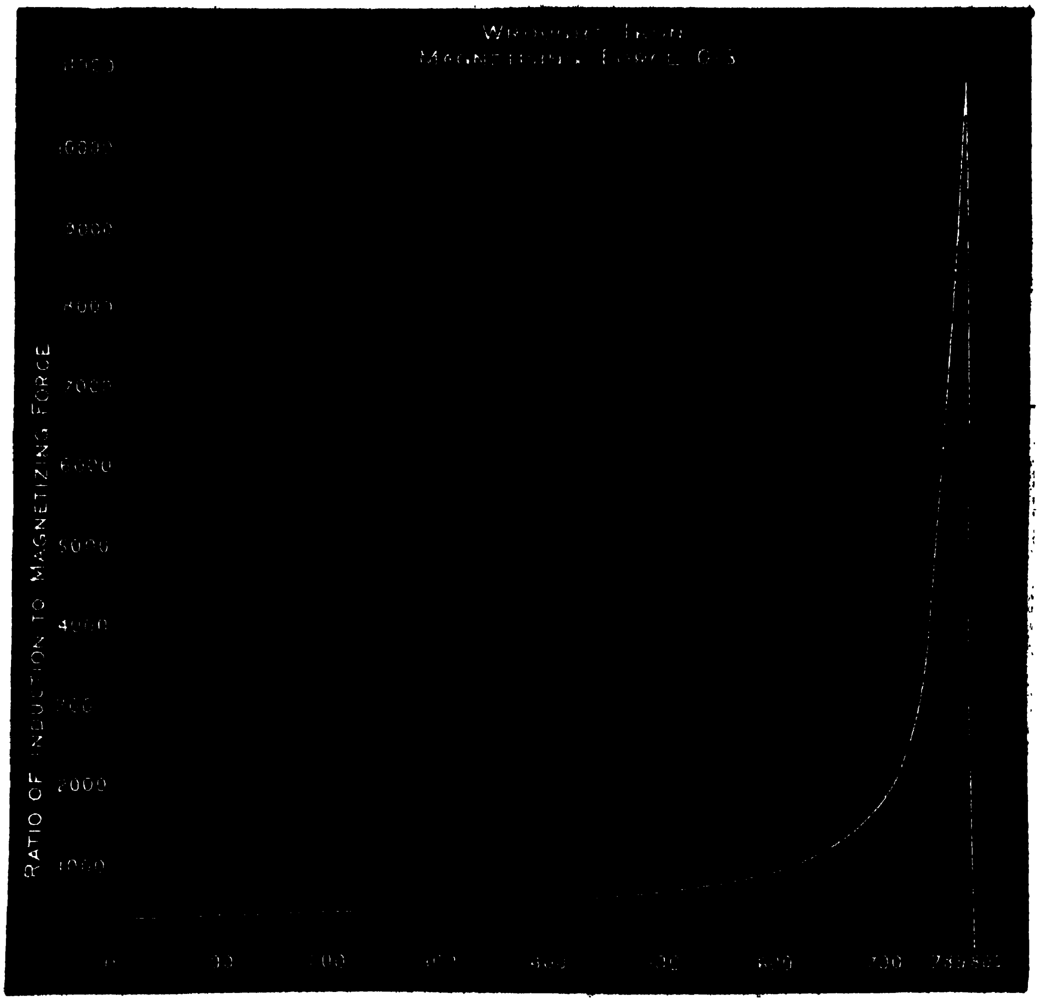

FIG. 8.

first, and rapidly at the end. It is also very greatly to diminish the coercive force, and to increase the facility with which the body is magnetized. To give an idea of the magnetizing forces in question, the force for Fig. 8 was 0·3; and as you see from Figs. 9 and 10, the force ranges as high as 60. Now the earth's force in these latitudes is 0·43, and the horizontal component of the earth's force is 0·18. In the field of a dynamo machine the force is often more than 7000. In addition to the general characteristics of the curve of magnetization, a very interesting, and, as I take it, a very important, fact comes out. I have already stated that if the ring be submitted to a great current in one direction, which current is afterwards gradually reduced to zero, the ring is not in its non-magnetic condition, but that it is, in fact, strongly magnetized. Suppose now we heat the ring, whilst under the influence of a strong magnetizing current, beyond the critical temperature at which it ceases to have any magnetic properties, and that then we reduce the current to

[1] Inaugural Address delivered before the Institution of Electrical Engineers, on Thursday, January 9, by J. Hopkinson, M.A., D.Sc., F.R.S., President. Continued from p. 254.

zero, we may in this state try any experiment we please. Reversing the current on the ring, we shall find that it is in all cases non-magnetic. Suppose next that we allow the ring to cool without any current in the primary, when cold we find that the ring is magnetized; in fact, it has a distinct recollection of what had been done to it before it was heated to the temperature at which it ceased to be magnetic. When steel is tried in the same way with varying temperatures, a similar sequence of phenomena

FIG. 9.

FIG. 10.

FIG. 11.

is observed; but for small forces the permeability rises to a lower maximum, and its rise is less rapid. The critical temperature at which magnetism disappears changes rapidly with the composition of the steel. For very soft charcoal iron wire the critical temperature is as high as 880° C.; for hard Whitworth steel it is 690° C.

The properties of an alloy of manganese and iron are curious. More curious are those of an alloy of nickel and iron. The alloy of nickel and iron containing 25 per cent. of nickel is non-magnetic as it is sure to come from the manufacturer; that is to say, a substance compounded of two magnetic bodies is non-magnetic. Cool it, however, a little below freezing, and its properties change: it becomes very decidedly magnetic. This is perhaps not so very remarkable: the nickel steel has a low critical temperature—lower than we have observed in any other magnetizable body. But if now the cooled material be allowed to return to the ordinary temperature it is magnetic; if it be heated it is still magnetic, and remains magnetic till a temperature of 580° C. is attained, when it very rapidly becomes non-magnetic, exactly as other magnetic bodies do when they pass their critical temperature. Now cool the alloy: it is non-magnetic, and remains non-magnetic till the temperature has fallen to below freezing. The history of the material is shown in Fig. 11, from which it will be seen that from −20° C. to 580° C. this alloy may exist in either of two states, both quite stable—a magnetic and a non-magnetic—and that the state is determined by whether the alloy has been last cooled to −20° C. or heated to 580° C.

Sudden changes occur in other properties of iron at this very critical temperature at which its magnetism disappears. For example, take its electrical resistance. On the curve, Fig. 12, is shown the electrical resistance of iron at various temperatures, and also, in blue, the electrical resistance of copper or other pure metal. Observe the difference. If the iron is heated, its resistance increases with an accelerating velocity, until, when near the critical temperature, the rate of increase is five times as much as the copper; at the critical temperature the rate suddenly changes, and it assumes a value which, as far as experiments have gone, cannot be said to differ very materially from a pure metal. The resistance of manganese steel shows no such change; its temperature coefficient constantly has the value of 0·0012, which it has at the ordinary temperature of the air. The electrical resistance of nickel varies with temperature in an exactly similar manner. Again, Prof. Tait has shown that the thermo-electric properties of iron are very anomalous—that there is a sudden change at or about the temperature at which the metal becomes non-magnetic, and that before this temperature is reached the variations of thermo-electric property are quite different from a non-magnetic metal.

Prof. Tomlinson has investigated how many other properties of iron depend upon the temperature. But the most significant phenomenon is that indicated by the property of recalescence. Prof. Barrett, of Dublin, observed that if a wire of hard steel is heated to a very bright redness, and is then allowed to cool, the wire will cool down till it hardly emits any light at all, and that then it suddenly glows out quite bright again, and afterwards finally cools. This phenomenon is observed with

great difficulty in the case of soft iron, and is not observed at all in the case of manganese steel. A fairly approximate numerical measurement may be made in this way: Take a block of iron or steel o ι which a groove is cut, and in this groove wind a coil of copper wire insulated with asbestos; cover the coil with many layers of asbestos; and finally cover the whole lump of iron or steel with asbestos again. We have now a body which will heat and cool comparatively slowly, and which will lose its heat at a rate very approximately proportional to the difference of temperature between it and the surrounding air. Heat the block to a bright redness, and take it out of the fire and observe the resistance of the copper coil as the temperature falls, due to the cooling of the block. Plot a curve in which the abscissæ are the times, and the ordinates the logarithms, of the increase of resistance of the copper coil above its resistance at the temperature of the room. If the specific heat of the iron were constant, this curve would be a straight line; if at any particular temperature latent heat were liberated, the curve would be horizontal so long as the heat was being liberated. If now a block be made of manganese steel, it is found that the curve is very nearly a straight line, showing that there is no liberation of latent heat at any temperature. If it is made of nickel steel with 25 per cent. of nickel, in its non-magnetic state, the result is the same—no sign of liberation of heat. If now the block be made of hard steel, the temperature diminishes at first; then the curve (Fig. 13) which represents the temperature bends round: the temperature actually rises many degrees whilst the body is losing heat. The liberation of heat being completed, the curve finally descends as a straight line. From inspection of this curve it is apparent why hard steel exhibits a sudden accession of brightness as it yields up its heat. In the case of soft iron the temperature does not actually rise as the body loses heat, but the curve remains horizontal, or nearly horizontal, for a considerable time. This, again, shows why, although a considerable amount of heat is liberated at a temperature corresponding to the horizontal part of the curve, no marked recalescence can be obtained. From curves such as these it is easy to calculate the amount of heat which becomes latent. As the iron passes the critical point it is found to be about 200 times as much heat as is required to raise the temperature of the iron 1 degree Centigrade. From this we get a very good idea of the importance of the phenomenon. When ice is melted and becomes water, the heat absorbed is 80 times the heat required to raise the temperature of the water 1 degree Centigrade, and 160 times the heat required to raise the temperature of the ice by the same amount. The temperature of recalescence has been abundantly identified with the critical temperature of

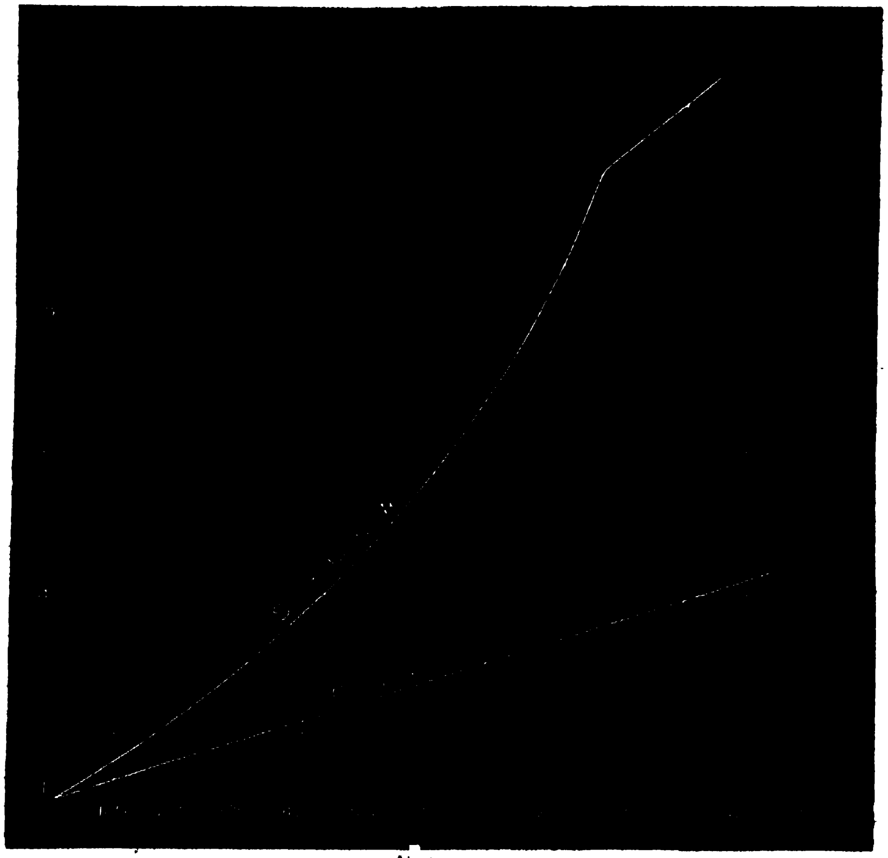

FIG. 12.

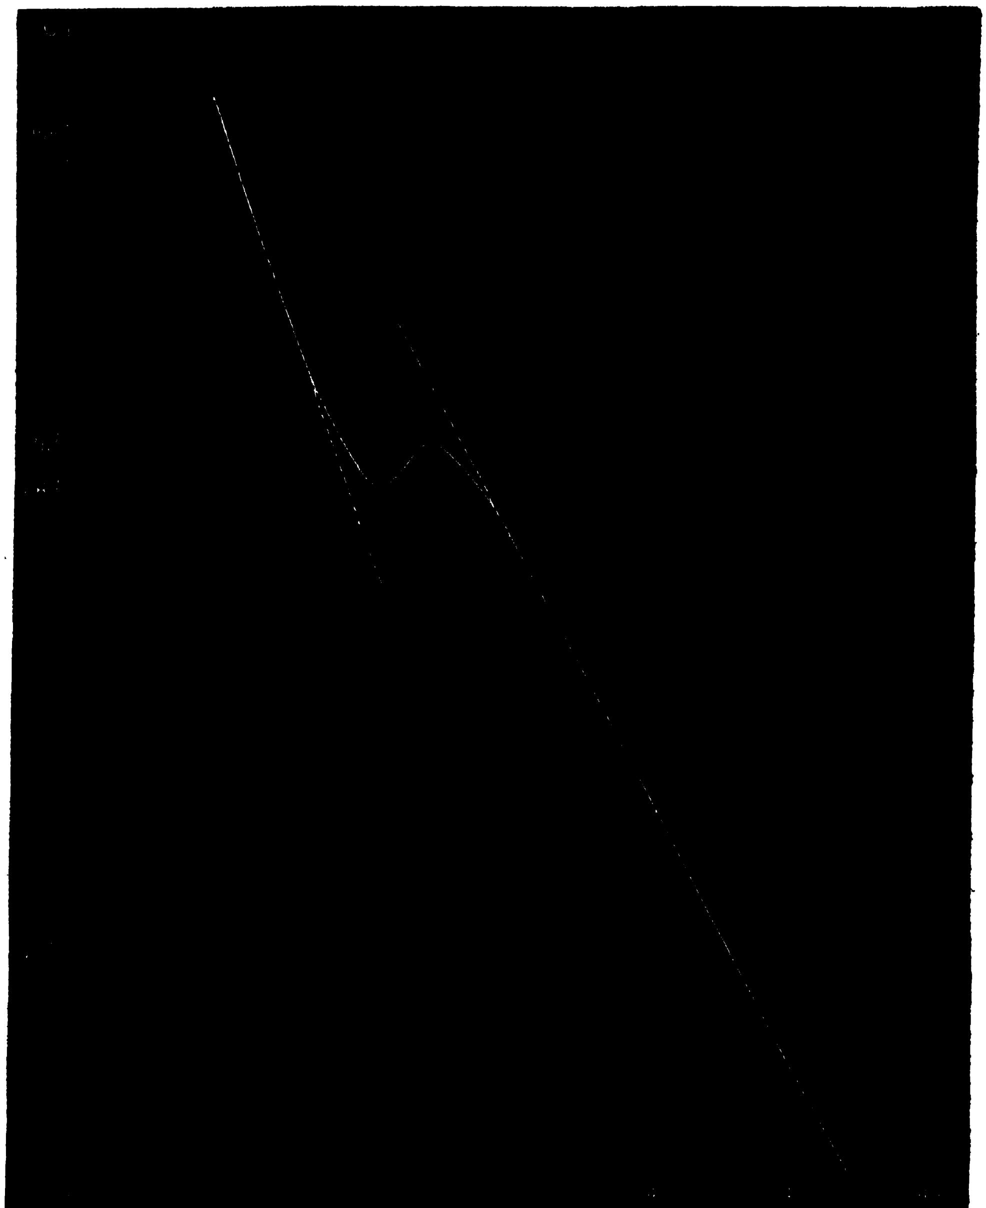

FIG. 13.

magnetism.[1] I am not aware that anything corresponding with recalescence has been observed in the case of nickel. Experiments have been tried, and gave a negative result, but the sample was impure; and the result may, I think, be distrusted as an indication of what it would be in the case of pure nickel. The most probable explanation in the case of iron, at all events, appears to be that when iron passes from the magnetic to the non-magnetic state it experiences a change of state of comparable importance with the change from the solid to the liquid state, and that a large quantity of heat is absorbed in the change. There is, then, no need to suppose chemical change; the great physical fact accompanying the absorption of heat is the disappearance of the capacity for magnetization.

What explanations have been offered of the phenomena of magnetism? That the explanation must be molecular was early apparent. Poisson's hypothesis was that each molecule of a magnet contained two magnetic fluids, which were separated from each other under the influence of magnetic force. His theory explained the fact of magnetism induced by proximity to magnets, but beyond this it could not go. It gave no hint that there was a limit to the magnetization of iron—a point of saturation; none of hysteresis; no hint of any connection between the magnetism of iron and any other property of the substance; no hint why magnetism disappears at a high temperature. It does, however, give more than a hint that the permeability of iron could not exceed a limit much less than its actual value, and that it should be constant for the material, and independent of the force applied. Poisson gave his theory a beautiful mathematical development, still useful in magnetism and in electrostatics.

Weber's theory is a very distinct advance on Poisson's. He supposed that each molecule of iron was a magnet with axes arranged at random in the body; that under the influence of magnetizing force the axes of the little magnets were directed to parallelism in a greater degree as the force was greater. Weber's theory thoroughly explains the limiting value of magnetization, since nothing more can be done than to direct all the molecular axes in the same direction. As modified by Maxwell, or with some similar modification, it gives an account of hysteresis, and of the general form of the ascending curve of magnetization. It is also very convenient for stating some of the facts. For example, what we know regarding the effect of temperature may be expressed by saying that the magnetic moment of the molecule diminishes as the temperature rises, hence that the limiting moment of a magnet will also diminish; but that the facility with which the molecules follow the magnetizing force is also increased, hence the great increase of μ for small forces, and its almost instantaneous extinction as the temperature rises. Again, in terms of Weber's theory, we can state that rise of temperature enough to render iron non-magnetic will not clear it of residual magnetism. The axes of the molecules are brought to parallelism by the force which is impressed before and during the time that the magnetic property is disappearing; they remain parallel when the force ceases, though, being now non-magnetic, their effect is nil. When, the temperature falling, they become again magnetic, the effect of the direction of their axes is apparent. But Weber's theory does not touch the root of the matter by connecting the magnetic property with any other property of iron, nor does it give any hint as to why the moment of the molecule disappears so rapidly at a certain temperature.

Ampère's theory may be said to be a development of Weber's: it purports to state in what the magnetism of the molecule consists. Associated with each molecule is a closed electric current in a circuit of no resistance; each such molecule, with its current, constitutes Weber's magnetic molecule, and all that it can do they can do. But the great merit of the theory—and a very great one it is—is that it brings magnetism in as a branch of electricity; it explains why a current makes a magnetizable body magnetic. It also gives, as extended by Weber, an explanation of diamagnetism. It, however, gives no hint of connecting the magnetic proporties of iron with any other property. Another difficulty is this: When iron ceases to be magnetizable, we must assume that the molecular currents cease. These currents represent energy. We should therefore expect that, when iron ceased to be magnetic by rise of temperature, heat would be liberated; the reverse is the fact.

So far as I know, nothing that has ever been proposed even attempts to explain the fundamental anomaly. Why do iron, nickel, and cobalt possess a property which we have found nowhere else in nature? It may be that at lower temperatures other metals would be magnetic, but of this we have at present no indication. It may be that, as has been found to be the case with the permanent gases, we only require a greater degree of cold to extend the rule to cover the exception. For the present, the magnetic properties of iron, nickel, and cobalt stand as exceptional as a breach of that continuity which we are in the habit of regarding as a well-proved law of Nature.

[1] I have only recently become acquainted with the admirable work of M. Osmond on recalescence. He has examined a great variety of samples of steel, and determined the temperatures at which they give off an exceptional amount of heat. Some of his results are apparent on my own curves, though I had assumed them to be mere errors of observation. For example, referring to my Royal Society paper, there is, in Fig. 38, a hint of a second small anomalous point a little below the larger one. And, comparing Figs. 38 and 38A, we see that the higher the heating, the lower is the point of recalescence; both features are brought out by M. Osmond. The double recalescence observed by M. Osmond in steel with a moderate quantity of carbon I would explain provisionally by supposing this steel to be a mixture of two kinds which have different critical temperatures. Although M. Osmond's method is admirable for determining the temperature of recalescence, and whether it is a single point or multiple, it is not adapted to determine the quantity of heat liberated, as the small sample used is inclosed in a tube of considerable mass, which cools down at the same time as the sample experimented upon.

NOTES ON A RECENT VOLCANIC ISLAND IN THE PACIFIC.

In 1867, H.M.S. *Falcon* reported a shoal in a position in about 20° 20′ S., and 175° 20′ W., or 30 miles west of Namuka Island of the Friendly or Tonga Group.

In 1877 smoke was reported by H.M.S. *Sappho* to be rising from the sea at this spot.

In 1885 a volcanic island rose from the sea during a submarine eruption on October 14, which was first reported by the *Janet Nichol*, a passing steamer, to be 2 miles long and about 250 feet high.

The U.S.S. *Mohican* passed it in 1886, and from calculation founded on observations in passing, gave its length as $1\frac{1}{10}$ miles, height 165 feet. The crater was on the eastern end, and dense columns of smoke were rising from it.

In 1887 the French man-of-war *Decres* reported its height to be 290 feet.

In the same year an English yacht, the *Sybil*, passed it, and a sketch was made by the owner, H. Tufnell, Esq., which is here produced.

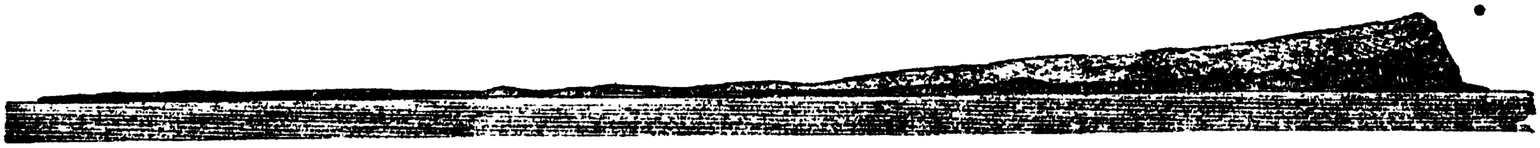
The island has now been thoroughly examined and mapped, and the surrounding sea sounded by H.M. surveying-ship *Egeria*, Commander Oldham.

It is now $1\frac{1}{10}$ mile long, and $\frac{6}{10}$ of a mile wide, of the shape given in the accompanying plan. The southern portion is high, and faced by cliffs on the south, the summit of which is 153 feet above the sea. A long flat stretches to the north from the foot of the hill.

The island is apparently entirely formed of ashes and cinders, with a few blocks and volcanic bombs here and there, especially on the verge of the hill.

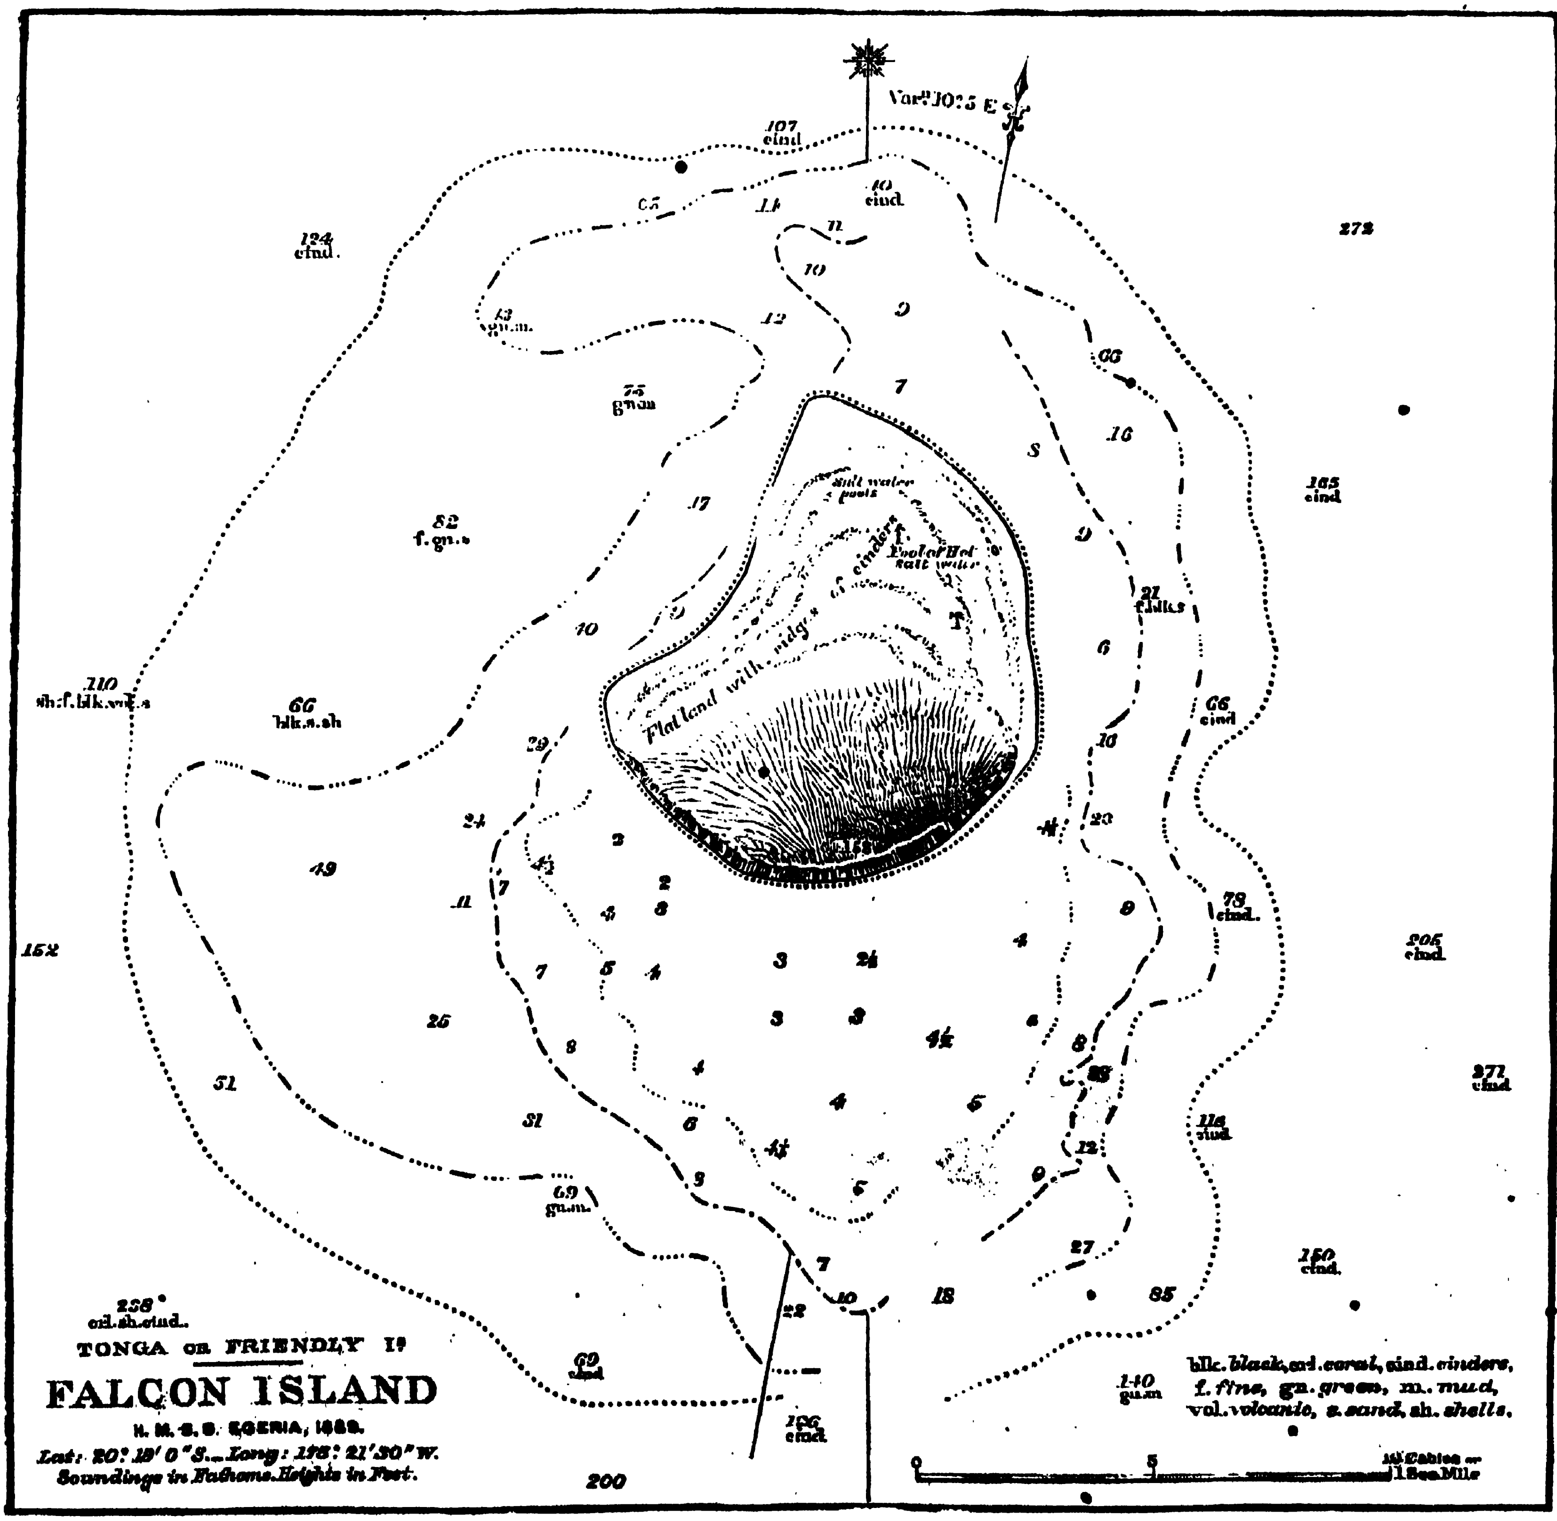
Under the action of the waves, raised by the almost constant south-east winds, this loose material is being rapidly removed; continual landslips take place, and Commander Oldham is of opinion that the original

By H. Tufnell, Esq., 1887, bearing S.E. about 2 miles.



By "Egeria," 1889, bearing E. 1½ mile.

By "Egeria," 1889, bearing N.N.W. ½ W. 1 mile.



summit was some 200 or 300 yards southward of the present highest cliff, and that the shallow bank stretching to the south represents the original extension of the island.

As far as can be judged from Mr. Tufnell's sketch from the north-west and that of the *Egeria* from the south-south-east, considerable changes have taken place in two years, the different summits shown in the former having disappeared as the sea has eaten away the cliffs.

The flat to the north seems to be partly due to redistribution under the lee of the island of the material removed from the southern face. It is crossed by curved ridges from 3 to 12 feet high, which Commander Oldham considers to have been formed as high beaches during spring tides and strong winds, the flat ground between them, almost at the level of the water, being deposited under normal conditions of weather.

The island is thus gaining on one side, while losing on the other, but when the high part has gone, this partial recovery will probably cease.

A little steam issuing from cracks in the southern cliffs was the sole sign of activity, but a pool of water at a temperature of from 91° to 113° F., water which rose in a hole dug in the flat of a temperature of 128° F., and a temperature of 100° F. in a hole dug half-way up the slope, also show that the island still retains heat near the surface. The water is sea-water that has filtered through the loose ashes, and it rose and fell with the tide.

It appears by the condition of the flat that the island has neither risen nor subsided during the past two or three years.

It will be interesting to watch the ultimate fate of this last addition to the Pacific isles, but it seems probable that its existence as an island will be short unless a hard core is yet revealed.

The soundings between Falcon Island and Namuka show that they are separated by a valley 6000 feet deep.

Metis Island, 73 miles north-north-east of Falcon Island, is another volcanic cone that appeared a few years before the latter, but has not yet been examined.

W. J. L. WHARTON.

WEATHER FORECASTING.

POPULAR interest in weather prediction shows no sign of abating. The January number of the *Kew Bulletin* is devoted to an account of Herr Nowack's so-called "weather plant," and its failure as an indicator either of coming weather or of earthquakes. Very recently a lively correspondence has been carried on in the daily press on the merits or demerits of the forecasts issued by the Meteorological Office. Accordingly, some remarks on the subject in the columns of NATURE may not be out of place.

One critic says that the forecasts are little better than haphazard guesses, and that the money devoted to them would be better spent on an additional lifeboat or two on the coast. Another says the forecasts are not worth the paper they are printed on, and wishes that the Office published in the newspapers fuller accounts of the weather reported from the coasts.

The fact is that the Office is compelled by public opinion to issue forecasts. The public *will* have its forecasts, as in 1867 it would have its storm-warnings, notwithstanding the reluctance of meteorologists to issue either the one twenty years ago or the other at present. It can hardly be doubted that, for these islands at least, conscientious meteorologists would be disposed to agree with Arago, who said in 1846, and printed it in italics in the *Annuaire du Bureau des Longitudes*: "Jamais, quels que puissent être les progrès des sciences, les savants de bonne foi et soucieux de leur réputation ne se hasarderont à prédire le temps." We are, of course, speaking of forecasts based on telegraphic reports, and emanating from a central office. In every country, without exception, where forecasts for distant counties or provinces are issued from headquarters, the complaints from outlying stations, of occasional failure, are frequent enough.

The fact is that at individual stations the percentage of success may be highly satisfactory, as at Mr. C. E. Peek's observatory at Rousdon, Lyme Regis. The results for this point appeared in the *Times* of January 14, and are as follows:—

	1	2	3	4	5	6	7
1884	58·7	69·0	20·0	11·0	73·4	16·9	9·7
1885	70·0	80·0	12·0	8·0	80·0	12·0	8·0
1886	73·0	80·0	11·0	9·0	85·0	8·0	7·0
1887	75·0	83·0	9·0	8·0	82·0	11·0	7·0
1888	81·0	89·0	5·0	6·0	89·0	7·0	4·0

In this, Col. 1 is percentage of reliable wind and weather.
Col. 2 ,, ,, wind only.
Col. 3 ,, wind doubtful.
Col. 4 ,, wind unreliable.
Col. 5 ,, reliable weather.
Col. 6 ,, weather doubtful.
Col. 7 ,, ,, unreliable.

On the other hand, at other points the forecasts may be frequently unsuccessful.

In one important particular not only our own Office, but all other Offices in Europe, signally fail, and that is the quantitative prediction of rain. No one is able, apparently, to predict whether the amount of rainfall on the morrow will be a tenth of an inch or a couple of inches. No sudden floods have ever yet been foretold. By this we are not speaking of predicting the approach of floods to the lower valleys from rain which has already fallen on the upper reaches of a river, for that is not meteorological prediction at all.

With the necessarily incomplete character of the information reaching head-quarters, the wonder is that the Office can attain such success as it does. The main deficiency in the information is in its quantity, and this seems to lie at the door of the Postal Telegraph Office, which insists on being paid for its telegrams. If meteorological messages were transmitted gratis, we might expect to hear at frequent intervals from our outposts, instead of twice, or, at most, thrice in the twenty-four hours: in fact, from several stations we can only hear once, the cost of more telegrams being prohibitive. It is self-evident that such an amount of information is quite insufficient. The weather will not abstain from changing because the hour for a telegraphic report has not arrived.

The information contained in the telegrams is also deficient in quantity, for the reporters cannot, within the prescribed form of their messages, communicate all the impressions which the ever-varying appearance of the sky may have conveyed to their minds. A skilled cloud observer, who has leisure to practise his powers, is often able to form a very correct idea of what is coming for the region bounded by his own horizon, but he is quite unable to give the benefit of his observations and experience to a friend in another county by telegraphing the information.

The greatest want which the Office finds in its observers is skill in cloud observation, and it appears to be the case that a cloud observer *nascitur non fit*, and that it is next to impossible to teach the art to a new hand, at least by correspondence.

Instrumental records of the phenomena taking place in the higher strata of the atmosphere are of course unattainable, and it is only by carefully watching the upper clouds that we can gain any notion of changes taking place up there, but, by means of such watching, Mr. Clement Ley is able to predict with nearly perfect certainty the weather for the Midlands—his own neighbourhood.

It must always be remembered that the forecasts are drawn for districts, not for individual stations; and disregarding the amount of correctness claimed by the Office by its own checking of its work, they attain a very creditable amount of success when tested by independent observers. This happens even in the summer-time, the very season at which a recent critic said that the forecasts for one month, if shuffled about, and drawn at random from a bag, would suit just as well for the next! This is proved by the results of the hay harvest forecasts, which are deduced from the reports of the recipients, practical agriculturists.

The following is the table for the season of 1888, the latest for which the figures are available:—

Districts.	Names of stations.	Percentages. Complete success.	Partial success.	Partial failure.	Total failure.
Scotland, N.	Golspie and Munlochy	48	34	17	1
„ E.	North Berwick, Glamis, Aberfeldy, and Rothiemay	43	41	11	5
England, N.E. ...	Chatton and Ulceby	50	27	17	6
„ E.	Thorpe and Rothamsted	48	39	10	3
Midland Counties..	Cirencester and East Retford ...	53	32	9	6
England, S.	Horsham, Maidstone, and Downton	52	40	6	2
Scotland, W.	Dumbarton, Islay, and Stranraer	45	41	8	6
England, N.W. ...	Leyburn and Prescot	57	24	11	8
„ S.W. ...	Bridgend (Glamorgan), Clifton, Glastonbury and Spring Park (Gloucestershire)	46	36	13	5
Ireland, N.	Moynalty and Hollymount	43	38	14	5
„ S.	Moneygall, Kilkenny, Ardfert Abbey	53	31	10	6

Every year the Office hears of farmers expressing their interest in these announcements, and sending daily to the places where they are exhibited, to learn what they contain.

To give an idea of the difficulty of obtaining accurate opinions from outsiders as to the value of storm-warnings, which are a class of forecasts, it may be interesting to give some specimens of reports.

Inquiries were made in 1882, from all the stations where signals are hoisted, as to their correctness and general utility. From Tynemouth the answer was that "these signals have been, and will be, an inestimable boon to our seafaring population." From South Shields, just opposite Tynemouth, the reply to a recent official inquiry was that "the warnings were not a ha'porth of use, and that no one minded them." Each answer merely represented the private opinion of the person who uttered it.

The reader can see that there is some difficulty in picking out the actual truth from such a heap of incongruous statements as the foregoing are certain to furnish.

R. H. S.

THE LABORATORIES OF BEDFORD COLLEGE.

BEDFORD COLLEGE, in York Place, Baker Street, which was one of the earliest institutions devoted to the higher education of women, is taking a leading part in providing facilities for their instruction in science. Founded long before Oxford and Cambridge condescended to the "weaker sex" (which has since proved strong enough to attain to the highest place in the Classical Tripos), it is the result of the work of enthusiasts who would not admit the possibility of defeat. It has had to struggle not only against the inevitable difficulties due to its early foundation, but against the apathy of London. Provincial towns feel that their honour is involved in the success of their institutions. The Colleges for women at Oxford and Cambridge share in the picturesque surroundings of those old homes of learning. They attract attention and interest by their situation amid scenes and traditions of which the whole English-speaking race is proud. Bedford College has had no such advantages. London institutions are regarded as either Imperial or parochial—as too large or too small to interest its citizens as such. Bedford Square compares unfavourably with the "backs," and it is impossible to regard York Place with that gush of emotion which "the High" sets free. Thus it is that, although Bedford College has been at work since 1849, and though one in every four of the whole number of women who have gained degrees of the University of London has been a student in its classes, the work of the College does not yet receive the meed of public appreciation which it has fairly earned. Bedford College is for women what University and King's Colleges are for men. It provides, within easy reach of all Londoners, an education which is tested by the severe standard of the University of London, and bears the hall-mark of success. One-third of its students are aiming at degrees, and their presence in the class-rooms, their work in the examination-hall, guarantees the quality of the teaching they receive to class-mates who do not intend to face the same ordeal. Science has for long been taught in Bedford College, but there has been a pressing need for better laboratories and class-rooms. These the Council has now provided. A new wing has been built, dedicated to the memory of the late Mr. William Shaen, who worked long and devotedly for the College. About £2000 is required to complete and fit up this building free of all debt, and Mr. Henry Tate, who had already given £1000 to the fund, has promised to supplement it by a like amount if the Council on its part can raise the other moiety of the deficit. It is too probable that this sum will only be obtained by an exhausting effort, but surely it is not too much to hope that the public may at last appreciate the importance of promoting the higher education of women in London. In a northern manufacturing town the money would be forthcoming in a week.

As regards the laboratories, it may be sufficient to say that Dr. W. Russell, F.R.S., is the Chairman of the Council, and that they have been built under his general supervision. They appear to be in all respects suited to the purposes for which they are intended. The physical laboratory and lecture-room are on the ground floor. The former has a concrete floor, and is well lighted, partly by windows, partly by a skylight. It looks out upon East Street, and is therefore removed as far as possible from the effects of the heavy traffic in Baker Street. The chemical laboratory is at the top of the house, and opens into a class-room which is fitted with all the usual conveniences for experimental illustration.

It is surely a hopeful sign that a College for the higher education of women should now be regarded as incomplete unless it controls physical and chemical laboratories specially designed and fitted for the delivery of lectures and the performance of experiments. These Bedford College now possesses. We can only hope that it may soon possess them free of debt. The Editor of NATURE will be happy to receive and forward to the College authorities any subscriptions which may be sent to him for that purpose.

STEPHEN JOSEPH PERRY, F.R.S.

ON the evening of January 4 a telegram from Demerara announced that there had been a successful observation of the eclipse of December 22, and that Father Perry had succumbed to dysentery.

Stephen Joseph Perry was born in London on August 26, 1833, and received his early education at Gifford Hall School. Having decided to enter the priesthood, he went

to the Catholic Colleges at Douai and Rome. While at Rome, he resolved to enter the Order of Jesuits; and, returning to England, he joined the English province of the Order on November 12, 1853. After two years' noviciate, he went to France for one year. He then returned to Stonyhurst for a course in philosophy. His inclination to mathematics was soon apparent, and his superiors in the Order decided to train him specially for this line of work. In 1858 he occupied the 6th place on the Mathematical Honours list of the London University. After attending lectures by De Morgan, he went to Paris for a year to finish his mathematical studies. On returning to Stonyhurst, he was appointed Professor of Mathematics and Director of the Observatory, succeeding Father Weld, who had for many years occupied the position. During the College year 1862-63, Father Perry taught one of the classes at Stonyhurst. In September 1863 he went to study divinity at St. Bueno's College, North Wales, and in 1866 he was ordained priest. Two years later he returned to Stonyhurst to resume his professorship and the charge of the Observatory. From this time he never left the College save to take part in some scientific expedition.

The work at Stonyhurst Observatory had been chiefly meteorological and magnetic before Father Perry's assumption of the directorship. In 1866 it was selected as one of the first-class meteorological stations. In 1867 the astronomical department of the Observatory was placed in a much more satisfactory position by the acquisition of an equatorial which originally belonged to Mr. Peters, and a small instrument destined for spectroscopic work. The first of these instruments was an 8-inch by Troughton and Simms, the second a $2\frac{3}{4}$-inch. The first spectroscope was procured in 1870 from Mr. Browning, and was used for preliminary work on star spectra, pending the construction of a larger instrument ordered from Troughton and Simms. In 1874 a large direct-vision spectroscope was ordered from Browning for use in observing the transit of Venus. Two years later a Maclean spectroscope was added, and in 1879 another by Browning containing 6 prisms of 60°; and more recently a Christie half-prism by Hilger.

With these instruments Father Perry has carried out systematic work of the highest class, his aim being to make Stonyhurst as efficient an observatory for solar physics as the means at his disposal would admit. His first communication to the Royal Astronomical Society indicates the policy he pursued—to undertake no work which was a mere duplication of that done at other places. His solar work during the last ten years formed the subject of a lecture at the Royal Institution on May 24. It may be divided into two classes—drawings and spectroscopic observations. For the drawings an image of the sun $10\frac{1}{2}$ inches in diameter was projected on a sheet of drawing-paper affixed to a sketch-board carried by the telescope, and all markings on the sun traced. The drawing finished, the chromosphere and prominences were examined with the spectroscope. About 250 drawings were made every year from 1880. The results of the observations were published annually in a neat little volume, and also in various publications.

In addition to this work, regular observations of Jupiter's satellites, comets, &c., were made, as also spectroscopic observations of comets, stars, &c.

Father Perry's labours were not confined to the Observatory alone, and in fact the extraneous work which he undertook gave the world the best opportunities for studying his high character, and impressed astronomers with a sense of his great devotion to their science. The first occasion on which he left the Observatory for scientific work was in the autumn of 1868, when, accompanied by Father Sidgreaves, he made a magnetic survey of the west of France. In the following year the vacation was spent in a like work for the east of that country. In 1871, assisted by Mr. Carlisle, he made a similar survey of Belgium.

In 1870, Father Perry took part, for the first time, in an eclipse expedition, being stationed near Cadiz, whither he had taken the two spectroscopes acquired by the Observatory in 1870, and two telescopes—a Cassegrain of $9\frac{1}{3}$ inches and a 4-inch achromatic. In 1874 he volunteered for the Transit of Venus expeditions, and was selected by Sir George Airy as chief of the Kerguelen party. Much tact and energy were required for the success of his party, who encountered several obstacles before arriving at the "Island of Desolation," as he termed Kerguelen. The spirit in which these obstacles were met is shown by his words—"We were determined that no consideration should make us flinch where the astronomical interests of the expedition were at stake." That this was no vain boast is proved by the evidence of those who were his colleagues in any excursions by water. His sufferings from sea-sickness were so fearful that everyone wondered that he cared to venture on even the most promising trip; aad that he should have undertaken the terrible voyage to Kerguelen speaks volumes for his enthusiasm for science. "Four days and nights the mighty waves had been washing over the *Volage*." His patience in suffering on this and other occasions helped to win for him the esteem of the officers with whom he came in contact. Not one word of his discomfort is to be found in any of the journals kept by him. In addition to the work of the expedition, he took magnetic observations at the Cape, Kerguelen, Bombay, Aden, Port Said, Malta, Palermo, Rome, Naples, Florence, and Moncalieri, and lectured on the Transit of Venus at the Cape and Bombay, and, on his return, at the Royal Institution.

In 1882 he went to Madagascar for the Transit of Venus. For the eclipse of August 29, 1886, he went to Carriacou, for that of August 19, 1887, to Russia; and last November he sailed for Salut Isles on his final expedition. It is worthy of remark that the Archbishop of Demerara, who had been a pupil of his, went to Barbadoes in 1886 to see his old master; and on the present occasion the body of the master was taken to Demerara.

When at Stonyhurst, Father Perry, in addition to his Observatory work, carried out to the fullest extent his duties as a professor. He was very popular as a lecturer; and at Liverpool, Wigan, and neighbouring towns, he often delighted audiences, some of which numbered more than 3000 people. Father Perry but rarely occupied the pulpit of recent years, but he was much admired as a preacher. His sermons were marked by the earnestness which formed so distinguished a feature of his character.

To those who came in contact with him in connection with his scientific work, he endeared himself by his genial and retiring manner, retiring on all occasions save when some sacrifice was demanded for the science he loved so well, and for which he laid down his life on December 27.

In 1874, Father Perry was elected a Fellow of the Royal Society, and very shortly before his last voyage he was placed on its Council. He was a Fellow and Member of Council of the Royal Astronomical Society, and a Fellow of the Royal Meteorological Society, the Physical Society of London, and the Liverpool Astronomical Society. Of the last-named Society he was President at the time of his death. In 1886 he received the honorary degree of D.Sc. from the Royal University of Ireland, and at various dates he was elected by the Accademia dei Nuovo Lincei, the Société Scientifique de Bruxelles, and the Société Géographique d'Anvers. For several years preceding his death, he served on the Committee of Solar Physics, appointed by the Lords of the Committee of Council on Education, and also on the Committee for Comparing and Reducing Magnetic Observations, appointed by the British Association for the Advancement of Science. In April 1887 he took part in the International Astrophotography Congress held at Paris.

MR. DANIEL ADAMSON.

As a mechanical engineer and a metallurgist, Mr. Daniel Adamson must always maintain a foremost place, for he was in the van in the industrial progress of the century. He was born at Shildon, in the county of Durham, in 1818, and apprenticed to Mr. T. Hackworth, locomotive superintendent of the Stockton and Darlington Railway, with whom he remained from 1835 to 1841. He then held various stations in the same railway until 1850, and in 1851 he began business on his own account as an iron-founder, engineer, and boiler-maker.

From this time forward until quite recently Mr. Adamson has brought out many highly successful inventions in connection with the manufacture of boilers and the application of steam. The first of these was a flange seam for high-pressure boilers, patented by him in 1852, and well known as Adamson's flange seam. In 1856, Mr., now Sir Henry, Bessemer, read a paper before the British Association at Cheltenham describing his steel process, and one of the first to apply it was Mr. Adamson. Having satisfied himself by experimental trials of the quality of steel, he determined to use it for the manufacture of boilers; and Sir Henry Bessemer, when on May 9, 1888, he presented the Bessemer Medal to Mr. Adamson on behalf of the Council of the Iron and Steel Institute, referred with satisfaction to this circumstance, as being the turning-point in his own career, and as having given a start to the use of steel for general engineering purposes. Later on, when open-hearth steel was introduced by the late Sir William Siemens, Mr. Adamson made trial of it for boiler use, and was for years an upholder of the merits of steel. He wrote a comprehensive paper "On the Mechanical and other Properties of Iron and Mild Steel," which was brought before the Paris meeting of the Iron and Steel Institute in 1878, when it gave rise to a most interesting discussion. This paper is looked upon as a standard one on the subject of steel.

Mr. Adamson's inventions appear to have been all intimately connected with his business. In 1858 he applied hydraulic power for the riveting of steel structures, and in 1862 he brought out an invention for building steam boilers, the rivet holes being drilled through the plates when these were in position. He was entirely opposed to the punching of steel plates; he described it as a barbarous mode of treatment, as it tore the fibre of the material; and he would never allow it to be used in his own works. The important feature in all Mr. Adamson's work was its thoroughness; all the material used was subjected to chemical and mechanical tests, so that he obtained a reputation throughout the world for the soundness of everything he turned out.

Mr. Adamson was one of the first to show the superiority of compound engines. This class of engine had already been introduced by Mr. John Elder, of Glasgow, but to Mr. Adamson is greatly due the credit of the employment of triple and quadruple expansion engines. In 1874 he read a paper at Manchester, in which he maintained that pressures of 150 pounds on the square inch could be as safely applied as pressures of 50 pounds by a careful extension of the compound system. As far back as 1861 he patented and brought out a triple-expansion engine, and in 1873 a quadruple engine. In the paper to which we have just referred Mr. Adamson gave expression to the opinion that the consumption of coal per horse-power per hour should not exceed from 1 to $1\frac{1}{2}$ pounds of coal, whilst at that time $2\frac{1}{2}$ pounds per horse-power per hour was considered a very good result.

Besides these inventions, Mr. Adamson took out patents in connection with the manufacture of steel by the Bessemer process, with machinery for compressing steel, and for testing machines, as also improvements in guns and armour.

No account of his work would be complete without a reference to his connection with the Manchester Ship Canal. He was of an enthusiastic temperament, and this was made specially evident in connection with this great undertaking. A Manchester man, and thoroughly convinced of the benefit which would accrue to the surrounding manufacturing towns, Mr. Adamson set to work to effect what others had proposed. It is more than 65 years ago since it was proposed that Manchester should be connected with the sea by a ship canal, but it was Mr. Adamson's invitation to various persons to meet at his house on June 27, 1882, that really started the project. The proceedings then initiated resulted in the incorporation of the Manchester Ship Canal Company in 1885. Mr. Adamson's work in connection with international progress, and his labours to make Manchester an ocean steam port, will not readily be forgotten.

In September and October last he was engaged on an examination of the iron mines of the island of Elba, and he embodied the results in a report to the Italian Government. About two months ago he caught a cold on his Flintshire estate of Wepre Hall. He returned to his home at Didsbury, and died there on Monday, the 13th inst.

Quite recently Mr. Adamson was elected President of the Iron and Steel Institute. He was a member of the Institution of Civil Engineers, of the Institution of Mechanical Engineers, and of the Iron and Steel Institute, and to the proceedings of these Societies he presented many papers containing the results of his inquiries as to the properties and treatment of metals, especially iron and steel.

NOTES.

At a meeting of a Committee appointed by the Council of the Royal Society to set on foot a memorial to the late James Prescott Joule, held on November 30 last, at Burlington House, it was unanimously resolved that a fund should be raised for a memorial of an international character commemorative of the life-work of Joule. This memorial will have for its object the encouragement of research in physical science. It is proposed also that a tablet or bust shall be erected to his memory in London, a Manchester Memorial Committee having already taken steps to ensure a suitable monument in his native city. Joule's discoveries were of such commanding importance that there can be no doubt as to the success of this movement. The Committee feel confident not only that men of science will gladly contribute towards a fund to do honour to Joule's memory, and to assist others to follow in his footsteps, but that those who devote themselves to the practical application of scientific principles will also be anxious to aid in the promotion of a fitting memorial of one whose work has exerted so great an influence on industry.

We regret to announce the death of Gustave-Adolphe Hirn, the eminent physicist. He died at Colmar on January 14, in his seventy-fifth year.

Mr. Rooney, who accompanied the late Father Perry on the solar eclipse expedition to the Salut Isles, has arrived in England, bringing with him the plates successfully exposed during the totality of the eclipse by Father Perry and himself. Mr. Rooney has put himself in communication with the Astronomer Royal, and the plates will be handed over to the Royal Astronomical Society to be developed.

The Forth Bridge was tested by the engineers on Tuesday as a preliminary to the passage of the first train over it on Friday. The following is the official report:—"Sir John Fowler and Mr.

Baker, engineers of the Forth Bridge, have to-day tested the two 1700-feet spans by placing on the centres two trains, each made up of 50 loaded coal waggons and three of the heaviest engines and tenders, the total load thus massed upon the spans being the enormous weight of 1800 tons, which is more than double what the bridge will ever be called upon in practice to sustain. The observed deflections were in exact accordance with the calculations of the engineers, and the bridge exhibited exceptional stiffness in all directions." Every part of the bridge will be in perfect order for the visit of the Prince of Wales on March 4.

AT the meeting of the Convocation of London University, on Tuesday, there was some discussion as to the question of the reconstitution of the University. Dr. F. J. Wood, who presided, said he was not in a position to help Convocation very much. As they were well aware, the Senate had drawn up a scheme which was intended to follow on the lines of the recommendations of the Royal Commission. That scheme had been submitted to the consideration of University College and King's College, and up to now those Colleges had arrived at no decision upon it, but requested a conference. That conference was about to take place, and, of course, until it was held it was impossible for any of them to say what shape the scheme would ultimately assume. Mr. T. Tyler moved a resolution declaring that "The proposal of the University for London Commission that, under a new charter for this University, special powers and privileges should be conferred on certain institutions in or near London is incompatible with the fair and just treatment of the provincial Colleges, and that the acceptance of this proposal would be detrimental alike to the interests of the provincial Colleges and to those of the University itself." This motion was unanimously adopted.

ON Friday, January 24, at 4.30 p.m., Mr. Holland Crompton will begin a course of ten lectures at the Central Institution, Exhibition Road, on the theory of electrolysis and the nature of chemical change in solution. In this course an historical account will be given of the recent development of the Clausius dissociation hypothesis by Arrhenius, Ostwald, and others; of van't Hoff's extension of Avogadro's theorem to dilute solutions; and of the Raoult methods of determining the molecular weights of dissolved substances. On Monday, January 27, at 4.30 p.m., Prof. Armstrong, F.R.S., will begin a special course of ten lectures on methods of analysis as applied to the determination of the structure of carbon compounds. The object of this course will be to explain and experimentally demonstrate the methods adopted in determining the structure of the more important and typical compounds, including alkaloids, carbohydrates, and oils and fats.

THE annual meeting of the Association for the Improvement of Geometrical Teaching was held last Friday morning in one of the theatres of University College, London, under the presidency of Prof. Minchin. While observing with pleasure that the Universities of Oxford and Cambridge had embodied in the printed regulations for various examinations some requests of the Association with regard to elementary geometry, the Council in their report expressed regret that the Euclid papers set for responsions at Oxford still consist exclusively of "book work." The response of the University of Dublin to the Society's petition is that they are not prepared to decide on such important questions without much consideration. At the afternoon meeting papers were read by the Master of St. John's College, Cambridge, on a new treatment of the hyperbole; by Mr. G. Heppel, on the teaching of trigonometry; by Mr. E. M. Langley, on some geometrical theorems; by Prof. Minchin, on statics and geometry; and by Mr. R. Tucker, on isoscelian hexagrams.

FEARS having been expressed as to a possible connection between influenza and cholera epidemics, Dr. Smolenski publishes, in the Russian *Official Messenger*, an elaborate report upon the subject. He points out that the suspicion is not new, and that in 1837 it was discussed by Gluge ("Die Influenza"), and refuted. In fact, influenza or *grippe* epidemics have been known in Europe since 1173—that is, for more than seven hundred years; whilst the first cholera epidemic appeared in Europe in 1823, but did not spread, that time, further than Astrakhan. Six years later it broke out in Orenburg; next year in Caucasia and Astrakhan again, whence it spread over Russia, and, in 1831, reached Western Europe. As a rule, influenza spreads very rapidly, and in 1782, at St. Petersburg, no fewer than 40,000 persons fell ill of it on the same day (January 14). In 1833 its progress was also very rapid, and within a few days it appeared at places so far apart as Moscow, Odessa, Alexandria, and Paris, while cholera epidemics are usually slow in their migrations from one place to another. Moreover, influenza is chiefly a winter epidemic, while cholera prefers the spring and the summer. Dr. Smolenski has further tabulated all influenza and cholera epidemics which have broken out in the course of our century in Europe, and he comes to the following results:—Influenza broke out in 1816, in Iceland; 1827, in Russia and Siberia; 1830–33, in Europe generally; 1836-37, in Europe; 1838, in Iceland; 1841-48 and 1850–51, in Europe; 1853, in the Faroe Islands; 1854-55 and 1857–58, in Europe; 1856, in Iceland and the Faroe Islands; 1862, Holland and Spain; 1863-64, France and Switzerland; 1866, France and Great Britain; 1867, France, Germany, and Belgium; 1868, Turkey; and 1874-75, Western Europe. As to the cholera epidemics during the same period they were: 1823, Astrakhan and Caucasia (from Persia); 1829, Orenburg (from Turkestan); 1830, Russia (from Persia); 1831–37, various parts of Europe; the next epidemic appeared in 1846 in Transcaucasia (coming from Persia); in 1847 it spread over Siberia and Russia, and in 1848 it was in Europe; in 1849–52 it was followed by feeble outbreaks all over Europe. The third cholera epidemic came from Persia again in 1852, and it resulted in a severe outbreak during the years 1853–55 in Europe, followed by feebler outbreaks till 1861. The fourth cholera epidemic came through the Mediterranean ports in 1865, and lasted in Europe till 1868, with feebler epidemics in 1869–74. The latest invasion of cholera was in 1884, when it came again through the Mediterranean ports. As to the cholera epidemic which now begins to die out in Persia and Mesopotamia, it certainly is a danger—the more so as, out of the five epidemics of cholera which have visited Europe, three have come from Persia.

ATTENTION has lately been called to the fact that anchovies are found off Torquay and other south coast fishing centres. Prof. Ewart, of Edinburgh, has written to the *Times* that during the present winter they have made their appearance in the Moray Firth. At the end of December they were abundant off Troup Head, where considerable numbers were captured in the herring nets by the Buckie fishermen. Prof. Ewart thinks that further inquiries may perhaps show that the northward migration of the anchovies is in some way related to the mildness of the winter. He points out that it is most desirable to ascertain whether they have reached the Moray Firth with the warm Atlantic water that during western winds rushes through the Pentland Firth, or by travelling along the east coast through the cold Arctic water that wells up from the bottom in the vicinity of the Dogger Bank.

THE programme of the Royal Horticultural Society for the present year includes a daffodil exhibition and conference, to be held at Chiswick on four days of April; the great show in the Temple Gardens in May; an exhibition of tea roses, by the National Rose Society, in June; in July an exhibition of and

conferences upon carnations, ferns, and selaginellas; and in September, at Chiswick, exhibitions of and conferences upon dahlias and grapes. The drill-hall meetings began with one on the subject of winter gardening, introduced by the Rev. W. Wilks; and, after the annual meeting in February, there are to be papers and discussions upon hippeastrums (amaryllis), salad ings, spring flower gardening, spring flowering shrubs and trees, herbaceous pæonies, lilies, fruit-drying, hollyhocks, crinums, trees and shrubs for large towns, and Chinese primulas. The accommodation at the drill-hall is not adequate to the wants of the Society, and the Council is considering whether it would not be possible to erect a suitable building on the Thames Embankment.

THE International Horticultural Exhibition to be held in Berlin under Royal and Imperial auspices, from April 25 to May 5, will be characterized by two special features—an exhibition of horticultural architecture, and one of horticultural models, apparatus, &c. It is requested that all exhibits or announcements of such should be promptly sent to the General Secretary of the Society for the Promotion of Horticulture, Prof. Dr. L. Wittmack, Invalidenstrasse 42, Berlin N., from whom all further information may be obtained. The Exhibition will be held in the Royal Agricultural Exhibition building, on the Lehrt Railway. The general organizer of the scientific department is Prof. Dr. Pringsheim; and the following gentlemen have undertaken the management of special branches:—For the geography of plants, Prof. Dr. Ascherson; for physiology, Prof. Dr. Frank; for seeds, Herr P. Hennings; for morphology, anatomy, and the history of development, Prof. Dr. Kny; for fungi, Prof. Dr. Magnus; for soils, Prof. Dr. Orth; for history, literature, and miscellaneous, Dr. Schumann; for officinal and technical objects, Dr. Tschirch. The Minister for Agriculture, Dr. Freiherr v. Lucius-Balhausen, will be the Honorary President of the Exhibition. The city of Berlin has granted the sum of 15,000 marks towards its expenses; and a guarantee fund of 80,000 marks has been raised.

THE Calcutta Herbarium contains a rich collection of Malayan plants, and Dr. King, the superintendent of the Calcutta Royal Botanic Garden, proposes to publish from time to time a systematic account of as many of them as are indigenous to British provinces, or to provinces under British influence. In addition to the States on the mainland of the Malayan penninsula, these provinces include the islands of Singapore and Penang, and the Nicobar and Andaman groups. The classification which Dr. King intends to follow is that of the late Mr. Bentham and Sir Joseph Hooker. The current number of the Journal of the Asiatic Society of Bengal contains the first of this proposed series of papers.

THE January number of the *Kew Bulletin* contains an able and most interesting report, by Dr. Francis Oliver, on the so-called weather plant. This plant is *Abrus precatorius*, Linn., a well-known tropical weed. Mr. Joseph F. Nowack claims to have discovered that its leaves have "the peculiar property of indicating by their position various changes in nature about forty-eight hours before the said changes occur." Numerous observations with hundreds of such plants have convinced him that "any given position of the leaves corresponds always to a certain condition of the weather forty-eight hours afterwards." Some time ago he devised an apparatus for the purpose of putting his supposed discovery to practical use. It consists of a "transparent vessel containing the weather plant, closed on all sides, protected against injurious external influences, and adapted to be internally ventilated and maintained at a temperature of at least 18° Reaumur, these being the conditions under which, in temperate climates, Nowack's weather plant answers the purpose of a weather indicator." Last year Mr. Nowack was anxious that his apparatus should be scientifically tested at Kew, but it would not have been easy for any member of the staff of the Royal Gardens to find time for the necessary observations. The task was undertaken by Dr. Francis Oliver, who now presents the results of his investigation. The following is a summary of the conclusions at which he has arrived:—"I contend that all the movements exhibited by the leaves of *Abrus precatorius* depend on causes not so far to seek as those suggested by Mr. Nowack. The ordinary movements of the leaflets, of rising and falling, are called forth in the main by changes in the intensity of the light. In a humid atmosphere they are more sluggish than in a relatively dry one. In other words, when the conditions are favourable for transpiration the movements are most active. The position for snow and hail is connected intimately, in the cases that have come under my observation, with a spotting or biting (by insects) of the leaflets, and is not due to any other external factor. The position for fog and mist, and for electricity in the air, is probably due to the disturbance caused by varying light, the rhythmical movements of the leaflets being temporarily overthrown. The position indicating thunder and lightning I take to be pathological from its tendency to recur on the same leaves. Daily movements of the rachis constitute a periodic function in this as in many other plants with pinnate leaves. The regularity of these oscillations is considerably influenced by both light and temperature."

ON Tuesday an Archæological Congress began its proceedings at Moscow. The sitting was attended by delegates from German, Austrian, and French Archæological Societies. The section of the Russian Imperial Historical Museum in Moscow allotted to the Moscow Archæological Society was formally opened on January 8, by Prince von Dolgoroukoff, the Governor-General. The collection consists of a variety of antiquities from the Caucasus, stone and glass ornaments, beautiful enamel work from various parts of Russia, ancient holy images, and antique garments and china. A correspondent of the *Times*, who gives an account of the exhibits, calls attention especially to a number of ancient gold ornaments from the Caucasus (described as Merovingian), contributed by the Countess Ouvarova, the President of the Society. He also refers to certain Osetinian copper pins, 18 inches long, found near some human skulls, and supposed to have been used for dressing the hair. A helmet of Assyrian form has attracted much notice.

IN one of the lectures he is delivering at Aberdeen, under the Gifford Bequest, Dr. E. B. Tylor offered a most interesting suggestion the other day as to the meaning of a well-known but puzzling Assyrian sculptured group. This group consists of two four-winged figures, with bodies of men and heads of eagles, standing opposite a tree-like formation, which is easily recognized as a collection of date-palms, or a conventionalized representation of a palm-grove. Each of the two figures carries in the left hand a bucket or basket, in the right a body which each seems to be presenting to the palm-tree. What is this body? It is usually described as a fir-cone, but some have regarded it as a bunch of grapes, others as a pine-apple. Dr. Tylor suggests that it should be connected with the most obvious point of interest for which the date-palm has been famous among naturalists since antiquity—namely, its need of artificial fertilization in order to produce a crop of edible dates. This process in its simplest form consists in shaking the pollen from the inflorescence of the male date-palm over the inflorescence of the female. The practice is mentioned by Theophrastus and Pliny, and in modern times in such works as Shaw's "Travels in Barbary." Dr. Tylor exhibited a drawing of the male palm inflorescence, and said it was hardly necessary to point out the resemblance to the object in the hand of the winged figure of the Assyrian sculpture. As the cultivator of the palm-tree has to ascend the tree in order to perform the process of fertilization,

he of course takes with him a supply of fresh flowers in a basket. Dr. Tylor's theory, therefore, is that the objects carried by the winged genii of the Assyrians are the male inflorescence of the date-palm in one hand, the basket with a fresh supply of inflorescence in the other, and that the function the genii are depicted in the sculptures as discharging is that of fertilizing the palm-groves of the country—a function which must have been held to denote their great beneficence, since it showed them fulfilling the great duty of providing the Assyrians with bread.

THE current quarterly statement of the Palestine Exploration Fund contains a brief review of the work done in connection with the Fund during 1889. It is stated that excavations on property belonging to a French gentlemen on the eastern slope of Zion have revealed a number of rock-hewn chambers, which appear to have been used in ancient times partly as dwellings and partly as storehouses. In describing them Herr Schick remarks that nearly all the ground covered by the city of Jerusalem is found on examination to be honeycombed with these rock-hewn chambers. It is not improbable that the Jebusites were to some extent troglodytes. In the Apocryphal Acts of the Apostles mention is made of a cave at Cyprus "where the race of the Jebusites formerly dwelt."

SEVERAL violent shocks of earthquake occurred in Carinthia on January 14, at 9.30 p.m., their direction being from south-east to north-west. In the theatre at Klagenfurt, which was densely packed, the seismic disturbance caused a panic, which was heightened by a false alarm of fire. The audience, however, soon became reassured, and there was no accident to life or limb.

THE Pilot Chart of the North Atlantic Ocean for the month of January states that December was notable for the severe storms that prevailed along the Transatlantic routes. A number of the depressions followed each other in rapid succession; the most notable of these was one on the 16th, in about lat. 51° N., long. 37° W. Gales of hurricane force, with mountainous seas, accompanied this disturbance, as it moved to the north-eastward, to the serious embarrassment of west-bound steamers. Two storms occurred to the eastward of Bermuda during the first week of the month. The first of these disturbances was central on the 4th, in about lat. 36° N., long. 55° W. After 16 hours the wind hauled to south-east and moderated. The south-east wind experienced after the passage of the storm was probably due to the approach of the second cyclone, which was central on the 5th in about lat. 31° N., long. 63° W., and was accompanied by severe hailstorms and heavy seas. Very little fog was reported. A dense fog along the coast of the United States on the 19th, 20th, and 21st, extended some distance inland; navigation in New York harbour was practically suspended on the 20th. Ocean ice was reported in the neighbourhood of lat. 48° N., long. 47° W.

WE referred lately to a new kind of butter which is now being made in Germany from cocoanut milk. The Calcutta Correspondent of the *Times* says that the cocoanuts required for this industry are imported in large numbers from India, chiefly Bombay, and that the trade seems likely to attain still greater importance.

ACCORDING to the *Perseveranza* of Milan, quoted in the current number of the *Board of Trade Journal*, important sponge-banks have lately been discovered close to the island of Lampedusa, on the southern coast of Sicily. These deposits of sponges extend for over a surface of from 15 to 18 marine leagues, and are situated about an equal distance from the south-eastern extremity of the island. The smallest depth above these banks is 20 ells; the greatest depth is from 30 to 31 ells. At the lesser depths rock is met with, on which the sponge grows; at greater depths a sandy soil is found. All varieties of sponge are discovered here, including those which are in the greatest commercial request, and they are easy to obtain. Greek and Italian vessels have already proceeded to Lampedusa to take advantage of this discovery.

AT the meeting of the Linnean Society of New South Wales, on November 27, Mr. K. H. Bennett read a paper on the breeding of the glossy ibis (*Ibis falcinellus*, Linn.). The unprecedented rainfall of the year on the Lower Lachlan induced several species of birds to breed in the district, contrary to the author's experience of previous years. Among these was the glossy ibis, two nests of which with eggs of a beautiful green-ish-blue colour somewhat resembling those of *Ardea novæ-hollandiæ*, but much brighter, were found in October and November. At the same meeting Mr. J. H. Maiden communicated preliminary notes, by Dr. T. L. Bancroft, on the pharmacology of some new poisonous plants. Mr. T. P. Lucas read a paper on Queensland Macro-Lepidoptera, with localities and descriptions of new species. Forty-one species belonging to various families were proposed as new, and new localities were given for about ninety-five other species.

THE new number of "The Year Book of Pharmacy" (J. and A. Churchill) has been issued. It comprises abstracts of papers relating to pharmacy, materia medica, and chemistry, contributed by British and foreign journals from July 1, 1888, to June 30, 1889. It presents also the Transactions of the British Pharmaceutical Conference at the twenty-sixth annual meeting, held at Newcastle-on-Tyne, September 1889.

MESSRS. E. AND F. N. SPON have issued a third edition of "A Guide for the Electric Testing of Telegraph Cables," by Colonel V. Hoskiær, of the Royal Danish Engineers. The first edition appeared in 1873. The Congress of Electricians in 1881 made some alterations necessary, and the author explains that he has added a few methods of testing, in the hope of making the book more useful.

THE Society for Promoting Christian Knowledge has issued, in the series entitled "Chief Ancient Philosophies," a third edition of the Rev. I. Gregory Smith's "Aristotelianism," in which an attempt is made to tabulate from the "Ethics" the opinions of Aristotle on questions relating to what has been called "the scientific basis of morality." In the same volume is printed a treatise, by the Rev. W. Grundy, Head Master of Malvern College, on the more important of Aristotle's other works.

SOME interesting properties and reactions of the chlorides of selenium are described by M. Chabrié in the current number of the *Bulletin de la Société Chimique de Paris*. Selenium tetrachloride, $SeCl_4$, was obtained by Berzelius by passing a stream of chlorine over selenium at the ordinary temperature, a quantity of the reddish-brown liquid subchloride, Se_2Cl_2, being first formed, and eventually converted to the pale yellow solid tetrachloride. The tetrachloride was subsequently volatilized by heating and obtained in small white opaque crystals. By heating the crystals obtained by this method in one end of a sealed tube to 190°–200° C., M. Chabrié has obtained a sublimate of much larger and better formed crystals, presenting brilliant faces. With these crystals determinations of the vapour density of the tetrachloride were attempted by Victor Meyer's method at 360° in an atmosphere of nitrogen. The resulting numbers show that two molecules of $SeCl_4$ dissociate at 360° into one molecule of Se_2Cl_2 and three molecules of chlorine. The subchloride, Se_2Cl_2, is a very much more stable body, and may be distilled unchanged at 360°. Determinations of the density of its vapour yield values closely approximating to 7·95, the theoretical density of a molecule of the formula Se_2Cl_2. Among the numerous reactions of these compounds which M. Chabrié has studied, the most interesting are those between selenium tetrachloride and

benzene. It is curious that when pure benzene is allowed to react upon pure $SeCl_4$, the latter body undergoes precisely the same decomposition as when heated to 360°, the liberated chlorine reacting with the benzene to form several chlorbenzenes and all the selenium remaining in the form of Se_2Cl_2. If, however, the benzene and selenium tetrachloride are brought together in presence of that most useful of intermediate reagents, aluminium chloride, quite a different series of changes occur. On treating the mixture with water, and separating and distilling the oil obtained, three distinct fractions may be collected. The first, which passes over at 131°–133°, consists of monochlor benzene, C_6H_5Cl. The second, distilling at 227°–228° under a pressure of only a few millimetres of mercury, consists of phenyl selenide, $(C_6H_5)_2Se$, corresponding to phenyl sulphide, $(C_6H_5)_2S$, and phenyl oxide, $(C_6H_5)_2O$. It is a yellow oil of sp. gr. 1·45 at 19°·6. The third fraction, boiling between 245° and 250° under the same reduced pressure, consists of another new compound of the composition $Se_2(C_6H_5)_3C_6H_4Cl$. This substance is a red oil of sp. gr. 1·55 at 19°·6. On allowing this red oil to stand it deposits yellow crystals of a compound of powerful odour, which may be obtained recrystallized from alcohol in long rhombic prisms. On analysis this substance turns out to be seleno-phenol, C_6H_5SeH, analagous to thiophenol and mercaptan, both of evil odour. Like all the hitherto investigated mercaptans, its alcoholic solution readily reacts with salts of mercury and silver. Analysis of the silver salt leads to the formula C_6H_5SeAg. The reactions by which phenyl selenide and seleno-phenol are respectively produced are believed by M. Chabrié to be as follows:—

$$2C_6H_6 + SeCl_4 = (C_6H_5)_2Se + 2HCl + Cl_2,$$
$$C_6H_6 + SeCl_4 = C_6H_5SeH + 2Cl_2.$$

THE additions to the Zoological Society's Gardens during the past week include a Black-headed Gull (*Larus ridibundus*), British, presented by Mr. E. Hart, F.Z.S.; a Chinese Jay Thrush (*Garrulax chinensis*) from China, presented by Sir Harry B. Lumsden, C.B., K.C.S.I., F.Z.S.; a King Parakeet (*Aprosmictus scapulatus* ♂) from Australia, presented by the Rev. A. J. P. Matthews, F.L.S.; a Peregrine Falcon (*Falco peregrinus*) from Scotland, presented by Mr. Geo. W. Landels; a Vulturine Eagle (*Aquila verreauxi*), a Jackal Buzzard (*Buteo jacal*), a White necked Raven (*Corvultur albicollis*) from South Africa, presented by Mr. Marshall; a Pigmy Cormorant (*Phalacrocorax africanus*), a Moorhen (*Gallinula chloropus*), two Shining Weaver Birds (*Hypochera nitens*), four Black-bellied Weaver Birds (*Euplectes afer* 2 ♂ 2 ♀), two Abyssinian Weaver Birds (*Ploceus abyssinicus* ♂ ♂), four Red-beaked Weaver Birds (*Quelea sanguinirostris* 2 ♂ 2 ♀), four Cutthroat Finches (*Amadina fasciata* 2 ♂ 2 ♀), four Orange-cheeked Waxbills (*Estrelda melpoda*), a Paradise Whydah Bird (*Vidua paradisea* ♂) from West Africa, an Indian Silver-Bill (*Munia malabarica*) from India, two Cardinal Grosbeaks (*Cardinalis virginianus* ♂ ♂) an Indigo Bird (*Cyanospiza cyanea* ♂) from North America, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on January 23 = 6h 12m. 44s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) The General Catalogue description of this nebula is as follows: "Planetary nebula; pretty bright, very small, very little extended." So far as I know, the spectrum has not yet been recorded, but if it is of the same nature as other planetary nebulæ, bright lines may be expected. The character of the chief line, near λ 500, if visible, should be particularly noted.

(2) Dunér classes this with stars of Group II., but states that the type of spectrum is a little uncertain. He notes, however, that the bands 2, 3, and 7 are visible, so there seems to be no reasonable doubt about the type. The probability is that it is either an early or late star of the group, in which case we should not expect to find all the bands fully developed. The star has been provisionally placed in species 2 of the subdivision of the group, but further observations are at once suggested to determine whether this is right or wrong. If right, the bright flutings of carbon should be fairly prominent, as it is probably due to the masking effects of these flutings that some of the dark bands are absent. The carbon flutings near 517 and 474, seen in the spectrum of a bunsen or spirit-lamp flame, should therefore be particularly looked for. It is possible, too, that in the earlier stars of the group the hydrogen lines may appear bright, as the swarms are only a little more condensed than those constituting stars with bright lines, so that the interspacial radiation may more than balance the absorption.

(3) According to the observations of Konkoly, this is a good example of stars of the solar type. The usual observations, as to whether the star belongs to Group III. or to Group V., are required.

(4) A star of Group IV. (Gothard). The main point to be noted in stars of this class is the relative intensities of the lines of hydrogen and those of iron, magnesium, and sodium, for the purpose of arranging them in a line of temperature. If possible, the criterion lines which indicate increasing or decreasing temperature should also be noted, as in the stars which have hitherto been classed as of the solar type.

(5) This is a star of Group VI., showing the usual carbon flutings and the subsidiary bands 4 and 5 (Dunér). In some stars of the group of smaller magnitude, a greater number of secondary bands have been noted, and it seems possible, therefore, that 74 Schj. may not have been observed under the most favourable conditions. Further confirmatory observations are therefore necessary before conclusions as to the specific differences between the different stars of the group can safely be drawn.

(6) The spectrum of this variable has not yet been recorded. The period is 305·7 days, and the range from 8·2–10·6 at maximum to < 13 at minimum (Gore). The maximum occurs on January 23.

(7) This variable star has a period of 244·5 days, and ranges from 7–8·7 at maximum to < 13 at minimum. The spectrum is of the Group II. type, and the range of variability is such that the appearance of bright lines at maximum may be expected, as in R Leonis, &c., observed by Mr. Espin. The maximum occurs on January 25. A. FOWLER.

THE CLUSTER G.C. 1420 AND THE NEBULA N.G.C. 2237.—Dr. Lewis Swift, in the *Sidereal Messenger* for January 1890, calls attention to a wonderful nebulous ring entirely surrounding this cluster. The ring was discovered by Prof. Barnard last year (*Astr. Nach.*, 2918), and its average outer diameter estimated as not less than 40′, so that in comparison the ring nebula in Lyra is a pygmy. Although Dr. Swift discovered, in 1865, a large diffused nebula north-preceding the star-cluster G.C. 1420, his attention was first directed to the ring structure by Prof. Barnard in January 1889.

The nebula N.G.C. 2237 is in the constellation Monoceros; its position is R.A. 6h. 24m. 48s., Decl. + 5° 8′; hence it will soon be favourably situated for observation, and Dr. Swift hopes that Mr. Isaac Roberts will be induced to photograph it, as a change both in brightness and form is suspected.

ON THE SPECTRUM OF ζ URSÆ MAJORIS.—An examination of seventy photographs of the spectrum of this star, taken on as many different nights at Harvard College, and beginning on March 27, 1887, has led Prof. Pickering to conclude that the K line is double at intervals of 52 days, and that, for several days before and after it is seen to be double in the photographs, it presents a hazy appearance. From the period assigned, it was predicted that the line should be double on December 8, 1889, and January 30, 1890, and the duplicity

was confirmed on the former of these dates by each of three photographs. Two more stars have been found having a similar periodicity—β Aurigæ and *b* Ophiuchi. The hydrogen lines of ζ Ursæ Majoris appear to be broader when the K line is double than when it is single. Several other lines are also seen double when the K line is double. Measures of the plates gave a mean separation of 0·246 millionths of a millimetre for a line whose wave-length is 448·1, when the separation of the K line, whose wave-length is 393·7, was 0·199.

The explanation of this phenomenon proposed by Prof. Pickering is that the brighter component of this star is itself a double star having components nearly equal in brightness, but too close to have been separated as yet visually, and some interesting results have been worked out which appear to support this hypothesis.—*American Journal of Science*, January 1890.

SPECTROSCOPIC OBSERVATIONS OF ALGOL.—A note on the motion of this star in line of sight has previously appeared (NATURE, vol. xli. p. 164). The detailed investigation of the six photographs taken at Potsdam is given by Prof. Vogel in *Astronomische Nachrichten*, No. 2947, from which the following is taken. Motion towards the earth is represented by a minus sign, and a motion of recession by a plus sign; both are expressed in geographical miles per second:—

Potsdam mean time. h.	Distance from minimum. h.		Motion in line of sight.
1888, Dec. 4, 6·6	11·4 after.	...	−5·0
1889, Jan. 6, 5·7	22·4 before.	...	+6·9
,, 9, 5·5	19·4 before.	...	+7·5
Nov. 13, 9·3	13·3 after.	...	−5·6
,, 23, 9·0	22·3 before.	...	+6·2
,, 26, 8·5	19·6 before.	...	+6·8

From these results it will be seen that, before minimum, Algol has an average motion of recession of 6·8 geographical miles per second, but after minimum it approaches the earth with an average velocity of 5·3 geographical miles per second. A reduction of the measures by the method of least squares shows the velocities per second to be—

Before the minimum, +5·3 geographical miles,
After the minimum, −6·2 ,,

which give an average motion of recession or approach = 5·7 miles. The entire system is found to be moving towards the earth with a velocity of 0·5 geographical miles per second.

GEOGRAPHICAL NOTES.

AT a meeting of the South Australian branch of the Royal Geographical Society, on November 1, 1889, Mr. Tietkens gave an account of his recent explorations in Central Australia. His expedition was despatched by the Central Australian Exploring and Prospecting Association, and consisted of a party of five persons, including a black tracker and a native boy. At one point of his journey, when the party came within sight of "an imposing range," Mr. Tietkens hoped to find a watercourse flowing from its slopes to Lake Amadeus. He was disappointed. No watercourse worth mentioning was discovered, nor any spring or place where water could collect. Mr. Tietkens discovered several ranges of hills, to which he gave names. One of the pleasantest places found by him he called Gill's Creek, after the hon. treasurer of the South Australian branch of the Royal Geographical Society. Here a stream flows from a range of hills through a gorge or glen of sandstone formation. "This," he says, "was a most beautiful spot, where a few days could be spent profitably, so the camels were unloaded, and Billy and myself went up the creek to explore its wonders. We found that the creek separated into three distinct channels. Following the principal one, we found the creek to be running through a glen with perpendicular cliffs 80 or 100 feet high on each side, and fully three miles in length. We returned to our charmingly situated camp late in the afternoon. . . . The water will not be found to be always running, but in the glen at the head of the creek, and which I have named after my sister Emily, large deep pools will be found, four or five chains long, 10 and 15 feet deep, and so shaded by rocks from the sun that they cannot be looked upon as otherwise than permanent." After the reading of the paper Mr. G. W. Goyder, Surveyor-General, expressing gratitude to Mr. Tietkens, said that although as an effort to increase the extent of Australian mineral and pastoral resources Mr. Tietken's expedition might have been a comparative failure, yet the route which he had travelled might serve as a most useful base for after-comers. His journey showed that no large large river, as had been hoped, flowed into Lake Amadeus, and only gave another proof that the interior of Australia consists of a series of low mountains with shallow basins, which in wet seasons form lakes and in dry seasons evaporate.

MESSRS. GEORGE PHILIP AND SON have issued an excellent map showing all Stanley's explorations in Africa from 1868 to 1889. Each expedition is distinctly marked in colour, and dated on the map; and a condensed account of the explorer's travels and discoveries is provided by Mr. E. G. Ravenstein.

THE SOURCES OF NITROGEN IN SOILS.[1]

THE number of this half-yearly Journal, issued last April, contains nineteen valuable contributions, covering a considerable portion of the large subject of agriculture. Many of them are of purely practical import, such as the report upon the previous year's prize farm competition, on implements exhibited at the Nottingham meeting, and on the Exhibition of thoroughbred stallions of February last. Among the articles of special scientific interest may be named "The History of a Field newly laid down to Permanent Grass," by Sir J. B. Lawes, F.R.S.; "Grass Experiments at Woburn," by W. Carruthers, F.R.S.; "The Composition of Milk on English Dairy Farms," by Dr. Paul Veith, and the Annual Reports of the scientific staff of the Society. The Journal contains 380 closely-printed pages, is well illustrated, and replete with tables and statistics. Among such a mass of information, all of which possesses important economic value, it is by no means easy to make a selection for special notice. The changes within the soil, in the formation of a meadow by Sir John Lawes, are, however, worthy of close attention at a time when grazing and stock-feeding appears to be the most popular remedy for the agricultural depression under which the country has so long suffered. These observations are also important scientifically, as they throw light upon the interesting question as to the sources of nitrogen in all soils. The gradual improvement of grass land, from the period when it is first laid down until it assumes the character of old pasture, is a well-known agricultural fact. The gradual increase in the amount of nitrogen per acre in the meadow selected by Sir John Lawes throws light upon this practical observation, and is recorded as follows:—"There can be no doubt that there has been a considerable accumulation of nitrogen in the surface soil during the formation of the meadow (1856 to 1888), amounting in fact to an average of nearly 52 pounds per acre per annum over the last twenty-three years. The question arises, Whence has this nitrogen been derived?" This is, as is well known, a controverted point. The balance in favour of this acccumulation of nitrogen within the soil is still large, even after every source of nitrogen in fertilizers employed, foods fed upon the land by live stock, rainfall, and from every other possible source is taken into account. Therefore, Sir John comes to the conclusion that the gain of nitrogen in the surface soil must have had its source either in the subsoil, the atmosphere, or both. There is much experimental evidence pointing to the conclusion that at any rate some deep-rooted leguminous plants derive a considerable quantity of nitrogen from the subsoil. Reasoning upon the question as to how far the whole of the accumulated nitrogen in the surface soil has been derived by deeply-searching roots from the subsoil, Sir John says, "On this point we think it may safely be concluded, from the results of the experiments of Boussingault and of those made at Rothamsted, many years ago, that our agricultural plants do not themselves directly assimilate the free nitrogen of the air by their leaves. But in recent years the question has assumed quite a new aspect. It now is, Whether the free nitrogen of the atmosphere is brought into combination within the soil under the influence of micro-organisms, or other low forms, and so serving indirectly as a source of nitrogen to plants of a higher order? Thus Hellreigel and Wilfarth have found, in experiments with various leguminous plants, that if a

[1] "The Journal of the Royal Agricultural Society of England," April 1889. (John Murray, Albemarle Street.)

soil free of nitrogen have added to it a small quantity of soil-extract containing the organisms, the plants will fix much more nitrogen than was otherwise available to them in the combined form. It further seemed probable that the growth and crop residue of certain plants favoured the development and action of special organisms. It is admittedly not yet understood, either in what way the lower organisms affect the combination, or in what way the higher plants avail themselves of the nitrogen thus brought into combination. . . . Should it be firmly established that such an action does take place in the case of certain plants, though not in that of others, it is obvious that part, at any rate, of the gain of nitrogen by the soil supporting the mixed herbage of grass land may be due to the free nitrogen of the air brought into combination under the influence of the action supposed." This must be regarded as an important concession to the view that nitrogen may be derived for the purposes of plant nutrition from the inexhaustible ocean of the atmosphere, and it will probably not be long before the vexed question of the sources of nitrogen in soils will be placed upon a more satisfactory basis.

JOHN WRIGHTSON.

Royal Society, December 5, 1889.—"A New Form of Wedge Photometer." By Edmund J. Spitta.

The author explained that his attention was called to the necessity of devising an arrangement of this nature during a series of experiments upon which he has for some time been engaged to ascertain the cause or causes of the discrepancy previously shown to exist when points of light are photometrically compared with objects of sensible size ("On the Appearances presented by the Satellites of Jupiter during Transit," *Monthly Notices R.A.S.*, vol. 48). This investigation has served to indicate that a portion of the error to which reference has been made arises from the wedge form itself when employed upon a disk of any appreciable area, for it will be remembered that hitherto this instrument has only been employed upon points of light such as is exhibited by the stars. Woodcuts are given to explain how this takes place, but it may be briefly stated, that as the field of view in a single wedge photometer is of necessity variable in intensity of absorption, so the *preceding* limb of a disk is not extinguished at the same part of the wedge, and so not at the same "wedge-reading," as the *following* limb. Hence when comparing two different sized disks it is not difficult to understand that an error in the "wedge-interval," technically so called, must inevitably occur. To meet this difficulty, the error resulting from which will of necessity vary with the size of the area under consideration, the new photometer has been devised.

It essentially consists of two wedges of neutral tinted glass, arranged to pass one another in equal proportions by the turning of a single milled headed screw. A little consideration suffices to show that by this exceedingly simple means, the field of view in the photometer must be absolutely uniform in density throughout its extent, but that its power of absorption can be increased or diminished by the shifting of the wedges in the manner described. Another improvement is submitted by the addition of a wheel of tinted glasses of varying density, which, by revolving in front of the eye-piece, enables the operator to employ the photometer upon objects having a wide range of intensity. The instrument in its complete form, is mounted on the *occulting eye-piece* (*Monthly Notices R.A.S.*, vol. 45) to afford the observer a means of hiding any object or objects not under examination for the time being, which it is needless to point out is a matter of great consideration in all photometric comparisons.

Mathematical Society, January 9.—J. J. Walker, F.R.S., President, in the chair.—The following communications were made:—On the deformation of an elastic shell, by Prof. H. Lamb, F.R.S.—On the relation between the logical theory of classes and the geometrical theory of points, by A. B. Kempe, F.R.S.—On the correlation of two spaces, each of three dimensions, by Dr. Hirst.—On the simultaneous reduction of the ternary quadric and cubic to the forms $Ax^2 + By^2 + Cz^2 + Dw^2$, $ax^3 + by^3 + cz^3 + dw^3$, by the President (Sir J. Cockle, F.R.S., Vice-President, in the chair).

PARIS.

Academy of Sciences, January 13.—M. Hermite in the chair.—On some new fluorescent materials, by M. Lecoq de Boisbaudran. In continuation of his recent communication the author has investigated zircon and $Z\beta$; tin dioxide and samaria; tantalum pentoxide and samaria; tin dioxide and $Z\alpha$; tantalum pentoxide and $Z\alpha$; tin dioxide and $Z\beta$; tantalum pentoxide and $Z\beta$. All these fluorescent substances are fresh examples of the number of spectra obtained from the same active material with different solid solvents. In combination with the agents the solvents must naturally always modify the wave-lengths of the bands as well as their constitution, while still leaving to the various spectra of the agents a family likeness, whereby their common origin may at once be recognized. But if the identity or diversity of two active materials has to be determined *by exact wave-length measurements*, then it becomes essential to operate with absolutely similar solid solvents.—Multiple resonances of M. Hertz's electric undulations, by MM. Edouard Sarasin and Lucien de la Rive. Certain experiments are here described, which tend to throw doubt on Hertz's well-known hypothesis on the undulatory propagation of electric induction. The reading of the paper was followed by some remarks by M. Cornu, who pointed out that it would now be necessary to receive with the greatest reserve the theoretical consequences drawn by M. Hertz from his remarkable researches, more especially as regards the measurement of the velocity with which the induction is propagated in a rectilinear conductor. His experimental method will have to be subjected to much careful study before it can be accepted as a demonstration of the identity of light and electricity.—On the relation between the electric and thermal conductivities of the metals, by M. Alphonse Berget. In a previous paper the author described an easy method for measuring, by means of simple determinations of temperature, the thermal conductivity of the different metals relative to that of mercury, whose absolute value had already been determined. He has now extended these determinations to copper, zinc, iron, tin, lead, and several other metals. The tabulated results show that the order of the conductivities is the same for heat and electricity, but that the relation of the mean coefficients of thermal and electric conductivity is not absolutely constant. Hence the law of their proportionality is only approximately correct, and subject to somewhat the same conditions as Dulong and Petit's law of specific heats.—Heat of formation of platinum tetrachloride, by M. L. Pigeon. A process is described for obtaining this substance in considerable quantities, and the heat of formation of the anhydrous chloride is determined at + 20·5 calories. To complete its thermochemical study M. Pigeon is now endeavouring to determine its heat of solution in water and that of its hydrate.—On the combinations of gaseous phosphoretted hydrogen with boron and silicium fluorides, by M. Besson. The boron compound has the formula $2BF_3.PH_3$, and is decomposed by water with liberation of gaseous phosphoretted hydrogen. The silicon compound was obtained in the form of small and very bright white crystals, their composition corresponding to two volumes of phosphoretted hydrogen gas to three of silicon fluoride or thereabouts. These and some other compounds that remain to be studied render the analogy between phosphoretted hydrogen gas and ammonia still closer.—On the state of equilibrium of a solution of a gas in a liquid, different portions of which are kept at different temperatures, by M. P. Van Berchem. These researches were made with hydrochloric acid and ammonia, their high coefficient of solubility facilitating the detection of slight differences of concentration. The results show that there exists a special state of equilibrium for solutions of gases if the lower part of the solution is cooled, and the upper part heated.—Note on the rotatory power of matezite and matezo-dambose, by M. Aimé Girard. Some numerical errors in the author's former papers on the rotatory power of these bodies (*Comptes rendus*, lxxvii. p. 995) are here rectified, and the author's fresh experiments confirm his previous conclusion that their rotatory power is absolutely identical.—Papers were submitted by M. Emile Picard, on the employment of successive approximations in the study of certain equations with partial derivatives; by MM. Maquenne and Ch. Tanret, on a new inosite ("racemo-inosite"); by M. Edouard Heckel, on the utilization and transformations of some alkaloids present in corn during germination; by M. A. Giard, on the relationship of the annelids and mollusks; by M. Léon Vaillant, on the bichique (*Gobius* and *Sicydium*) fisheries in the island of Réunion; by M. A. Vaissière, on *Prosopistoma variegatum* of Madagascar; and by M. Salomon Reinach, on the volcanic eruptions supposed to have taken place in France during the fifth century A.D.

BERLIN.

Physiological Society, December 27, 1889.—Prof. du Bois-Reymond, President, in the chair.—Dr. Augustus Waller, of London, demonstrated the electrical negative variation of the heart which accompanies the pulse. The demonstration was preceded by a short introductory description of the method by which it is possible to detect the negative variation accompanying each beat of the heart both in man and other normal animals. The peculiar position of the heart determines the special position of the equipotential lines for the cardiac muscle, and these then determine the way in which the electrodes must be applied to the outer surface of the body in order to obtain the most marked results. Thus, for instance, when one pole of the capillary-electrometer is applied to the head or right shoulder of a man, while the other pole is connected with his left hand, this arrangement is effective, and the mercurial meniscus in the electrometer can be seen to move synchronously with the pulse. When the poles are applied to the left shoulder and left foot, or left hand and left foot, or right hand and right foot, these arrangements are non-effective. In the horse, dog, and cat, results are obtained by connecting the fore-limbs with the hind-limbs through the electrometer; this is due to the fact that in these animals the heart is placed with its axis from right to left, thus dividing the body symmetrically into a front and hinder half. The demonstrations were made on a man, a horse, and a dog.—Mr. Auschütz exhibited an apparatus ("Schnellseher") for the stroboscopic examination of instantaneous photographs (twelve per second) of moving objects. The reproduction of the movements afforded by the instrument was very perfect.

STOCKHOLM.

Royal Academy of Sciences, January 8.—On our knowledge of the nature of the Antarctic regions, and on the desirableness of researches there as well planned and comprehensive as those which have been conducted by Swedish investigators in the Arctic regions during many years, by Baron Nordenskiöld. If contributions could be obtained from Australia, Baron O. Dickson and Baron Nordenskiöld would fit out a scientific expedition to the Antarctic regions to start from Sweden in 1891.—On remains of birds from the Saltholms Limestone (Upper Cretaceous) at Limhamn, in Scania, by Prof. W. Dames, of Berlin. (The right humerus, scapula, and coracoideum, of probably a wading-bird, being next the Enaliornis of the chalk of Cambridge, in England, the only European find of a Cretaceous bird. It has been named *Scaniornis Lundgreni*, Dam.)—Researches on oiazotiol combinations, by Herr Hector.—On Jurassic woods from Green Harbour, in Spitzbergen, by Prof. Schrenk, of Leipzig.—On the secretions of the digestion in the median intestines, and some phenomena in combination therewith in insects and Myriopoda, by Dr. G. Alderz.

THURSDAY, JANUARY 30, 1890.

THE HYDERABAD CHLOROFORM COMMISSION.

THE safety of anæsthetics is a subject of the deepest personal interest to everyone, either on his own account or on that of his family or friends. For this reason, the general public, as well as the medical profession, have been looking with interest for the Report of the Chloroform Commission which has lately been trying to work out the subject under the generous auspices of the Nizam and his Minister Sir Asman Jah. As we pointed out in NATURE of December 19, 1889, p. 154, two views regarding chloroform are commonly held. The one view is that it may kill by paralyzing the heart directly. The other is that it really kills by paralyzing the respiration, and only stops the heart indirectly through the asphyxia which quickly follows stoppage of the respiration. The first view is generally held in London, the second in Edinburgh, where it was strongly insisted on by the late distinguished surgeon Prof. Syme. As we learn from the Report now published, it was in consequence of his reverence for Syme's teaching, that Surgeon-Major Lawrie moved for the appointment of the Commission, which was generously granted by the Nizam's Government. This teaching was founded on clinical experience, but the results of some physiological experiments appeared to show that it was incorrect, and that chloroform paralyzed the heart directly. To ensure anything like general acceptance of Syme's teaching it was necessary that it should be shown that these experiments did not really disprove it. But this necessitated a complete revision of the whole question of the *modus operandi* of chloroform, and of the production of an immense amount of experimental evidence. This has been supplied by the present Commission, and the result of their labours appears to be that there is some truth in both views, but that when chloroform is given in the ordinary way by inhalation, it is the respiration which stops first. When chloroform vapour is blown down the trachea the heart may be stopped by it, but when the vapour is drawn into the lungs in the usual way by the movements of the chest, this is not the case, for, the respiratory movements being arrested first, their stoppage prevents any more chloroform vapour from being taken into the lungs. Embarrassment of respiration constitutes the first sign of danger, and should be at once attended to. The breathing should not be allowed to stop, but if it should do so by any accident, life may still be preserved by the immediate use of artificial respiration. Should the interval of asphyxia between the stoppage of natural breathing and the commencement of artificial respiration be too long, the heart may fail to such an extent that artificial respiration is in vain; and if the administrator waits for a failing pulse to warn him of danger, the warning may come too late. In a former research by the Glasgow Committee of the British Medical Association, some of the experiments, in the opinion of the Committee, seemed to show that chloroform not only lowers the blood-pressure and paralyzes the heart, but does so sometimes in an unexpected and capricious manner. The Commission has repeated their experiments, and found a similar fall of the blood-pressure and slowing of the pulse, but has come to a different conclusion regarding their causation, and attributes them not to chloroform but to asphyxia. If this opinion be correct, it shows how much care is necessary to avoid asphyxia, for the Glasgow Committee appear to have overlooked its presence, notwithstanding the serious effects it was producing on the heart in the animals on which they were experimenting. The work of the Hyderabad Commission points strongly to the conclusion that deaths from chloroform in man are likewise due to asphyxia, and the Commission considers that by careful attention to the respiration all deaths may and should be prevented. The Report points out that instead of the conclusions at which the Commission has arrived being opposed to those of Claude Bernard, they are almost exactly those at which that distinguished physiologist, so well known for his accurate work, had arrived, although his name is often quoted in support of the doctrine that chloroform kills by paralyzing the heart. The number of experiments on which the Commission bases its conclusions is very large, no fewer than 430 having been done without recording apparatus, and 157 with recording apparatus. The former consisted chiefly of experiments, firstly, on the general action of chloroform given in various ways, in various dilutions, and in different conditions of the animal, *e.g.* fasting, after meals, after a preliminary dose of spirits, &c.; and, secondly, on the limits within which artificial respiration could restore life, and the effect of morphine, strychnine, atropine, &c., in modifying the action of the anæsthetic and the reviving power of artificial respiration. The necessary apparatus was taken out by Dr. Lauder Brunton, and on his arrival at Hyderabad the Commission was at once constituted: Surgeon-Major Lawrie, President; Drs. Lauder Brunton, Bomford, and Rustamji, members; Dr. Bomford acting as secretary. They were greatly aided in their work by the members of the first Commission, Drs. Hehir, Kelly, and Chamarette, as well as to Messrs. Tripp, Carroll, and Mayberry, the latter of whom gave the chloroform. To Dr. Chamarette's energy and fertility of resource the success of the experiments was mainly due. The work was continued daily from 7 a.m. to 5 p.m., except on Sundays and holidays, from October 23 to December 18. From a speech made by Dr. Lauder Brunton at a dinner given to the Chloroform Commission by the Nawab Intesar Jung, we learn that the facilities for work afforded to the Commission were such as were not to be found even in the great laboratories of the continent of Europe; and, indeed, the large number of experiments which were made in a comparatively short time, is sufficient of itself to show this. At this dinner the Nawab Intesar Jung reminded his guests that Europe is indebted to Mohammedan writers of the schools of Bagdad and Cordova for the preservation of medical science during the dark ages; and as Dr. Lauder Brunton very truly said in his reply, the Nizam has not only followed the traditions of the Mussulmans in selecting the subject of research, but has rivalled the generosity of Haroun-al-Raschid and Abdurrahman in supplying the Commission with every-

thing it could require. Although the liberal endowment of universities and schools is now fortunately much more common, especially in America, than it used to be, yet there are few instances of such liberality as the Nizam has shown towards definite subjects of scientific research. For the excellent example they have shown in this matter, the Nizam and his enlightened Minister, Sir Asman Jah, deserve the thanks of the scientific world, while they also deserve that of the public in general for their endeavour to save life and lessen suffering by rendering the administration of anæsthetics so safe that they may be employed without fear whenever they are required.

HYGIENE.

Hygiene, or Public Health. By Louis C. Parkes, M.D. (London: H. K. Lewis, 1889.)

DR. LOUIS PARKES has conferred an important service by the opportune publication of his manual of hygiene. The public mind has been slow to perceive the importance of the science of preventive medicine. For nearly half a century Sir Edwin Chadwick and others have preached the doctrine. It fell for a long time on sterile ears. No doubt provisions have been made by Parliament from time to time, when some special danger or disease-cause was brought prominently into notice: not, indeed, as a part of a system of sanitary protection, but as if it were the only matter to be cared for. Thus, vaccination was made compulsory to stop small-pox, but for a long time many other diseases were ignored. These scattered efforts in sanitary legislation were brought to a focus in 1875, and systematic sanitation may be said to have been instituted by the division of the country into sanitary areas, and by the appointment of medical officers of health. These provisions were rather a theoretical recognition of the importance of the subject than a practical creation of efficiency, for the medical officers in a large number of instances have not received such remuneration as would enable them to give their whole time to their duties; nor do they possess security of tenure. They have been, for the most part, men in local practice, who have been content to receive an honorarium in some cases as low as £20 or £10, and occasionally even £5 and £3 a year. Such payments could not be expected to induce men to do more than give a nominal service to their official duties; and it is, indeed, notorious that in many instances the object of members of the sanitary authority which has made the appointment, who are themselves owners of house property, has been to nominate men who would let matters rest, and would not compel owners of cottages to spend money on sanitation.

We are now, however, entering upon a new era in sanitation. The creation of County Councils which took place last year has introduced a new feature. Although the powers vested in these bodies are permissive and somewhat tentative, it has already become quite certain that they will, sooner or later, bring the whole sanitary service of the country under their general supervision and control.

The Local Government Act of 1888 lays down the provision that the medical officer of health to be appointed by a county must be qualified in sanitary knowledge—that is to say, in the knowledge of the prevention of disease, as distinguished from curative knowledge. It will, therefore, be necessary that the men appointed shall have spent time and money in obtaining the required qualifications for their duties: hence they will expect adequate salaries to remunerate them for the trouble and expense which they will have incurred in thus educating themselves. The call for education in preventive medicine will react upon the medical schools and the various degree-conferring bodies—such as the Universities—and will compel them to hold examinations in, and to confer diplomas or certificates upon the possessors of, sanitary knowledge. Moreover, the sanitary authorities, in order to justify to themselves the higher salaries which they will be compelled to pay, will be induced to place enlarged areas under the medical officer, and, in order that he may effectually perform his duties, he will insist on being furnished with a better educated staff of sanitary inspectors or inspectors of nuisances than have been, as a rule, appointed under the old *régime*.

It is thus evident that there will soon be a great call for sanitary education, and Dr. Parkes's volume forms a very useful commentary upon what are the general heads comprised in a course of instruction in the methods necessary for applying various branches of science to the prevention of disease. A glance at the table of contents shows the very large field embraced under the title of preventive medicine. It concerns not only the medical man, but the engineer, the architect, the chemist, the physiologist, the meteorologist, and the statistician. The questions to be studied include climatic conditions; the effect on health of the state and movement of the atmosphere; the health of soils; the purity of water-supply, and the prevention of injury to health from fouled water; the construction of buildings, their warming, lighting, and ventilation; questions of food and clothing; the history of communicable diseases; and bacteriology, as well as hygienic chemistry and statistics.

A brief summary of the present position of our knowledge shows us that preventive medicine is still far removed from being an exact science. We have, no doubt, lately made much progress in removing from the medical man the imputation that his proceedings were empirical. Physiological studies in recent years have established the relationship between certain diseases and the presence of micro-organisms; and although this relationship may not be as universal as some persons would hold, yet we know that there is a positive relationship in the case of certain diseases. When the causes of diseases are known; when the action of the causes can be studied, and their mode of entrance into the body ascertained; when the methods which can be applied to their destruction are discovered; then the science of the prevention of disease ceases to be empirical.

Whilst, however, our progress in this knowledge has of late years been extremely rapid as compared with former experience; yet when, as in this volume, we are brought face to face with the various problems of the prevention of disease, we are amazed to find what a vast field is still unexplored in the knowledge of the causes of disease. Dr. Parkes has given a very interesting summary of our knowledge on this part of the question in his chapters on

contagia and communicable diseases. We may be said at present to be only standing on the threshold of this very intricate subject. Even in the case of those diseases which have been ascribed with the greatest assurance to the presence of organisms in the blood or the tissues, we are told that it is as yet uncertain whether the symptoms of disease are the results of the direct action of microbes themselves upon the tissues, or are caused by their indirect action in producing poisonous alkaloids or ferments. We have not yet elucidated the curious connection between the diseases of animals and mankind; but whilst we are gradually acquiring the conviction that some diseases from which animals suffer are communicable to the human race, it is at any rate satisfactory at the same time to have arrived at the certainty that those laws of cleanliness in air, soil, and water, which are the basis of human sanitation, are the most effective safeguards to be observed in the case of domestic animals, if certain classes of disease are to be avoided. But with all our increased knowledge of the existence and methods of propagation of the various forms of organisms which appear to co-exist with certain forms of disease, we have not yet discovered why certain diseases become epidemic at certain times, whilst they lie comparatively dormant at other times; Nature has not yet revealed all her secrets to the microscope or to the laboratory.

Take as an instance, the influenza which is now present with us. Its epidemics are historical. It has appeared over and over again at somewhat distant intervals. But we do not know why it comes at one time and not at another. It has been specially described on various occasions since 1557. In 1837 it covered the whole of the north of Europe in fifteen days. It travels as rapidly through sparsely inhabited as through populous countries. In 1780 it manifested itself in ships in mid-ocean, which had had no communication with the shore. The facts connected with its incidence are thus well known. Its progress would scarcely seem to be accounted for by contagion or infection in the common acceptance of the word. Is its present advent due, like the beautiful sunsets with which we were favoured a few years ago, as some observer suggests, to a catastrophe in some distant part of the globe? or is it owing, as M. Descroix, of the Meteorological Observatory at Montsouris, tells us, to the remarkably stagnant atmosphere of last autumn? Large populations agglomerated in towns depend, for the removal of the foul emanations continually passing into the atmosphere from their midst, upon the action of winds and storms, and these causes of ventilation were notably absent during the past autumn; and Dr. Descroix points out that the failure to remove this impurity would favour the propagation of organisms injurious to the health of the community, acting in this respect just as a festering drain or manure heap would act.

The advance which each separate science makes opens out new views to the hygienist, and this short reference to the epidemic of influenza serves to point out the extent of the subject, and to impress upon us the fact that it is almost impossible that a moderate-sized treatise by a single individual could form an adequate text-book for the student in these various and intricate questions.

Dr. Parkes's volume, admirable as it is in many respects, leaves something to be desired in its treatment of some of the subjects. We would especially refer to those relating to civil engineering and architecture, which are not the special subjects of a medical man. The treatment of these branches presents some weak points, and there is an occasional tendency to recommend specific inventions rather than to enunciate principles, which may somewhat militate against the general acceptance of the volume as a complete and permanent text-book.

It would have been better if the educational features of the book had been limited to those special subjects with which the profession of the author has made him most familiar. The work is, however, a convenient hand-book, and will serve as a valuable guide to show the student what are the several subjects which have to be studied; and in that sense we can safely recommend it as an adjunct to the library of every sanitarian.

IN THE HIGH ALPS.

Im Hochgebirge. Wanderungen von Dr. Emil Zsigmondy. Mit Abbildungen von E. T. Compton. Herausgegeben von K. Schulz. (Leipzig: Duncker and Humblot, 1889.)

THIS handsome volume possesses a melancholy interest, for it is in reality a memorial to a young and ardent mountaineer who was killed by a fall from a precipice in the year 1885. Emil Zsigmondy was by descent a Hungarian, but was born and educated in Vienna, where his father practised as a physician. The son followed the same profession, of which he was a distinguished student. As a boy he showed a love of mountain-climbing. At the age of fifteen, he and his brother Otto, without guides, made an ascent of the Reiseck, a peak 2958 metres high. The expedition occupied twenty-six hours, of which twenty-two were spent in actual walking, a remarkable feat of endurance on the part of two lads.

After this Emil made annually an Alpine excursion, the expeditions increasing in difficulty and (with the exception of one year) in number. The first of which a description was published was accomplished in his eighteenth year, and after this references to the journals of foreign Alpine Clubs and similar publications are frequent on the list. Altogether, as we are told in the brief biographical notice prefixed to this work, Emil Zsigmondy, though he perished a few days before completing his twenty-fourth year, had climbed nearly 100 summits of more than 3000 metres in height above the sea—in more than nine cases out of ten unaccompanied by guides. Most of the expeditions described in this volume have already appeared in various journals, and describe excursions which in themselves are not new; but many of them have this special interest, that they were made without guides. Sometimes the brothers were alone, but on the more difficult excursions they were generally accompanied by one or two trusty friends, such as Prof. Schulz, editor and part-author of this work.

The book is a record of Alpine expeditions told in plain but graphic language. It scarcely touches upon scientific questions, though we are informed that Emil was a student of Alpine botany, zoology, and geology, and published some observations on these subjects in a work which

appeared before his death. But now and then a chance remark indicates the geologist, and there is an interesting account of a remarkable appearance of the "Brocken spectre." This was witnessed from a rocky ridge near the summit of the Bietschhorn, a lofty peak on the southern side of the Bernese Oberland. The shadow of the observer was seen within a triple rainbow-ring. Of these rings, the inner one exhibited the usual tints; these were weaker in the second, and barely visible in the third. The shadow was larger than life, but was less than the diameter of the inner ring. By this, according to the text, it was encircled; but in the accompanying woodcut the shadow of the legs from below the knees is thrown upon the rings. The sun was getting low, and towards the west, for it was nearly 4 o'clock on an afternoon early in September. The wind came from the same direction, and the clouds were drifting eastwards from the mountain-peak. The "spectre" remained visible for nearly an hour, while the observers completed the ascent to the actual summit.

The illustrations are numerous, and some of them are not without a scientific value as faithful renderings of mountain scenery. It is seldom that the same can be said of similar engravings in English books. These, if no longer the caricatures which were formerly supposed to represent mountains, are still too often devoid of character. Mr. Whymper can and does give the outline of a mountain peak and the distinctive features of its rocks, but the ordinary illustrator is content with some conventional smudging which serves impartially for granite or limestone, for schist or slate, and is equally unlike each one of them, or, indeed, anything that exists on this earth. But as our artists are at length beginning to realize that Nature's workmanship is better than their own, and to follow the path which was trodden by Turner, Elijah Walton, Ruskin, and a few pioneers, we may hope that the illustrations of mountain scenery in English books may rise to the level of Continental publications, which, though not free from mannerisms, do make some attempt at accuracy. Those in the present work consist of eighteen full-page photogravures, copied apparently from water-colour drawings, and of a large number of woodcuts, which are in part from finished drawings, in part from pen-and-ink outline sketches. Many of the former are excellent, so also are some of the latter; but these are less successful in representing scenery than in recording little incidents in the mountaineers' experience. The simple unaffected narrative of adventure, in which there is evidence of skill in dealing with mountain difficulties, and courage, pushed, perhaps, sometimes to the border of rashness, is very pleasant to read, and it is sad to think that such a life has been lost to his many friends. The fatal fall occurred during an attempted ascent of the Meije, in Dauphiné, by a new route up the southern cliffs. Emil had climbed some distance above his two companions, when he fell from a cliff. They bravely attempted to check his descent by means of the rope which was attached to his waist, but it snapped under the strain, and the climber in a few moments lay lifeless on a glacier 2000 feet below. A full account of the accident was published in the *Alpine Journal* for 1885, which indicates that on this occasion more risk was being incurred than could be justified. T. G. B.

THE STORY OF CHEMISTRY.

The Story of Chemistry. By Harold Picton, B.Sc., With a Preface by Sir Henry Roscoe, M.P., D.C.L. LL.D., F.R.S. Pp. 386. (London: Isbister, 1889.)

It is a matter for surprise that, among the many books on the different branches of chemistry, so few are to be found devoted to the historical treatment of the science. The ordinary student in attempting to get an idea of the development of the subject labours under considerable disadvantages. From time to time, indeed, our professors are to be heard expounding "The Atomic Theory," "Joseph Priestley," "The Birth of Chemistry," and like topics; books on such subjects also exist. Our larger treatises, as a rule, have short historical introductions; text-books, too, occasionally contain information such as "the gas discovered by Rutherford in 1772 was subsequently named nitrogen by Chaptal." From such sources, however, a conception of the fundamental discoveries which have led up to the chemistry of to-day is only possible by dint of much searching, and at an expenditure of time far beyond that at the disposal of most students. A short history of the science in a handy form would be a decided acquisition to chemical literature. The name of the little volume before us is thus a promising one, and on perusal, the book in no way belies its title.

After showing who the alchemists were, and the state of chemical knowledge before they appeared on the scene, the author proceeds to divide his subject into nine periods. The first of these, "Alchemical Mysticism," extending from the time of the mysterious Hermes Trismegistus to that of Roger Bacon and Raymond Lully, includes also an account of Geber and Albertus Magnus. Next comes "Medical Mysticism," in which are sketches of Basil Valentine and his "Triumphant Chariot of Antimony," of Paracelsus and Van Helmont; followed by the "Decline of Mysticism," reaching down to the founding of the Royal Society of London by Charles II. in 1662, and embracing the work of Glauber and Helvetius. The fourth period, "The Beginnings of Science," deals with Boyle, Hooke, Mayow, and Hales. The reader's attention is then directed to Black's introduction of 'weighing" as a means of investigation. This chapter, which gives, besides, a pretty picture of Cullen, Black's instructor, constitutes the "Childhood of Truth." Then follows, under the heading of "The Conflict with Error," succinct account of the rise and progress of Stahl's phlogiston theory, with its bearings on the researches of Priestley, Cavendish, Scheele, and their contemporaries. Lavoisier's keen penetration and masterly deductions, "The Triumph of Truth," are then discussed, and lead up to "The Atomic Theory," Dalton's idea, and its later developments, from the time of Gay-Lussac, Ampère, and Avogadro, to that of Newlands and Mendeléeff. After a separate chapter on Davy and Faraday the book is brought to a close by short descriptions of the present state of inorganic and organic chemistry.

Mr. Picton's style is fresh and pleasing; his descriptions are clear and to the point. Whenever possible, brief surveys of the life and work of the men of science mentioned are given. Extracts from original writings are frequently quoted, and pains taken to enable the reader to form an idea of the general character of the individuals apart from their chemical discoveries alone. Chronological

order has not in every case been adhered to, the main idea and its subsequent development being frequently treated together; but the sequence of epoch-making events is strictly maintained. The work is quite up to date; when advisable, the author has introduced facts which have only been established by recent investigations.

The book is tastefully bound, and the illustrations are numerous. The latter are varied, and embrace cuts from "Die Zwölf Schlüssel," apparatus historic and modern, and portraits of celebrated chemists. To the reader possessed of some chemical knowledge the volume will be most useful, and to the uninitiated its earlier chapters, at least, cannot fail to be inviting.

LUMINOUS ORGANISMS.

Les Animaux et les Végétaux Lumineux. Par Henri Gadeau de Kerville. (Paris: J. B. Baillière et fils, 1890.)

THIS little book is a semi-popular summary of what is known in regard to the photogenous structures of the various kinds of luminous animals and plants, commonly (but improperly, as the author points out) known as phosphorescent. As it is on the whole fairly complete and accurate, being based largely upon the important researches of Panceri, Sars, R. Dubois, Emery, and others, it will probably be useful not only to amateurs, but also to students who wish to get a general knowledge of the range in organic nature of light-producing forms, and of the more important investigations on the subject which have been made since the days of Aristotle and Pliny.

Although the title-page of this book bears the date 1890, the important discovery by Giard, in September last, of luminosity in Amphipods which is due to an infectious disease is, it may be supposed, too recent to have been included—at any rate, it is not referred to.

After a short historical *résumé*, the first half of the work (170 pages) is occupied by a systematic account of those plants and animals which are luminous, commencing with the plants and then working up through the animal series from Protozoa to Vertebrata. More animals than plants are photogenous, and most of these are marine. Few observations have been made upon freshwater forms, and none are known from brackish water. M. Gadeau de Kerville takes care to point out, what is undoubtedly the case, that many supposed instances of luminosity, especially in dead animals or in the neighbourhood of harbours, &c., where there is much decaying organic matter, are due, not to any "phosphorescence" of the animal observed glowing, but to the presence of luminous Bacteria on the surface, in mucus, or in the tissues. Several species of light-producing micro-organisms (*Bacilli* and *Micrococci*) are already known, and the list will probably be largely added to in the future. It is, however, an excess of caution to doubt the claim of *Ceratium* (*Peridinium*) to be placed amongst photogenous genera, as two or three of the species appear to be responsible for a good deal of the "phosphorescence of the sea" around our western coasts in autumn—a phenomenon which is usually attributed even by naturalists to *Noctiluca miliaris*, although at such times it often happens that not a single *Noctiluca* is caught by the townet!

The well-known observations and experiments of Panceri on *Pennatula* and other forms are given, and the figures reproduced, and it will no doubt be useful to many to have the information obtained by various investigators thus collected into one volume. On p. 83 is given an observation by Quatrefages upon certain luminous *Talitri* (Amphipod Crustaceans) on the beach, which he supposed had derived their luminosity from contact with *Noctiluca*. Is it not more probable that, like Giard's diseased Amphipods at Wimereux (which, by the way, have turned up lately at Jersey, and will probably be found to be widely spread), they were infested by a photogenous microbe?

In connection with the remarkable "luminous globules" of some Schizopods (*Euphausia*, *Nyctiphanes*, &c.), M. Gadeau de Kerville suggests that these organs are light-perceiving, as well as light-producing, and that, therefore, the old designation of "accessory eyes" was not improperly applied. This view is supported by several observed cases where the true eyes of higher Crustacea were luminous; but it should be remembered that it is entirely opposed to the matured opinion given by G. O. Sars in his Report on the *Challenger* Schizopods.

Chapter xiii. is devoted to an account of the anatomy and physiology of the photogenous organs, in which, however, little of importance is added to what was given in the preceding part of the book. The author adopts the view of Dubois (founded upon experiments on *Pholas dactylus* made at the Roscoff Laboratory), that in all cases the luminosity is a purely physico-chemical phenomenon, and is dependent on the presence of two substances—the one (*luciférine*) soluble in water and obtainable in the crystalline state, the other (*luciférase*) a soluble ferment (like diastase)—which must be brought in contact in order that light may be produced. This seems going further than our present knowledge really warrants. The light-producing organisms and organs are so varied that it is possible that the causes of the luminosity may be manifold; and, at any rate in the higher forms, the bringing together of the *luciférine* and *luciférase* must be under the direct control of the nervous system, as the production of light is a reflex, perhaps in some cases a voluntary, action.

In a short chapter, entitled "Philosophie naturelle," the author considers, from the evolution stand-point, such questions as the origin of luminosity, the reason why only relatively small numbers of animals and plants are luminous, why the majority of luminous animals are marine, &c.; but for a discussion of these points, and also of the various uses (both to animals and to man) which the luminosity may have, reference must be made to the book itself, which, although some of the illustrations are poor, and there is unnecessary repetition and verbosity in the text, forms a readable and useful introduction to a very interesting and important subject.

W. A. HERDMAN.

OUR BOOK SHELF.

The Chemistry of Photography. By R. Meldola, F.R.S. (London: Macmillan and Co., 1889.)

THIS work is well worthy of study by serious devotees of photography. It enters, as its title indicates, into the chemistry of photography, and that in a very thorough and

easily understandable manner. There are some very few points in the author's explanations of phenomena as regards which we cannot quite agree with him. For instance, when he is considering the action of light on silver chloride he states that an oxychloride is formed (on the authority of Dr. Hodgkinson). That this is not always the case is shown by the fact that silver chloride is darkened when exposed in the presence of bodies which contain no oxygen, as, for instance, when the exposure is given in benzene. The author has adopted the plan of calling his chapters lectures, and in this instance we shall find no fault with what often is an artifice to cover slipshod writing, since the subject-matter is good, the language clear, and descriptive experiments are appended after each note in the narrative. We feel assured that if a student be fairly grounded in elementary chemistry and carries out these experiments, he will have a far better knowledge of the theory of photography than nine out of ten students possessed before this work was written. The author rightly points out that much in the theory of photography still requires elucidation, and with this we quite agree; but by putting into a connected shape those portions of the theory which may not require reconsideration, he has done much towards facilitating the solution of the remaining problems which are still *sub judice*.

The Popular Works of Johann Gottlieb Fichte. Translated from the German by William Smith, LL.D. With a Memoir of the Author. Fourth Edition. In Two Vols. (London: Trübner and Co., 1889.)

THESE volumes form part of the well-known "English and Foreign Philosophical Library." The translations included in them were first published in 1845-49, when German philosophy had only begun to attract attention in England. Fichte holds so clearly marked a place in the development of modern thought that it is still worth the while of students to make themselves familiar with his governing ideas; and there can be no disadvantage in their beginning with his popular rather than with his more systematic works. So far as the form of Fichte's teaching is concerned, it cannot of course be said to meet the needs of the present day. To many minds there is something even irritating in his use of large, abstract expressions, which are incapable of precise definition, and in the dogmatic tone in which he proclaims his convictions, as if he had somehow had special access to the sources of absolute truth. But his effort to solve the questions which lie behind the problems of physical science has at least the interest that belongs to perfect sincerity; and his methods and conclusions, whether they commend themselves to our judgment or not, are often in a high degree suggestive. He was personally of so manly and noble a character that his popular writings, in which he expressed his sympathies and tendencies freely, are perhaps more valuable from the ethical than from the strictly intellectual point of view. Dr. Smith's work as a translator is, we need scarcely say, excellent; and the like may be said of his work as a biographer. His memoir of the philosopher is written in a thoroughly appreciative spirit, and with adequate knowledge.

Travels in France. By Arthur Young. With an Introduction, Biographical Sketch, and Notes, by M. Betham-Edwards. (London: George Bell and Sons, 1889.)

EVERYONE who has given even slight attention to the pre-revolutionary period of French history knows, at least by hearsay, something about Arthur Young's "Travels in France." No other work of that time throws so clear and steady a light on the social and economic conditions which prevailed among the mass of the French people immediately before their great national convulsion. This is well understood by French historical students, who have found in the record of Young's observations a mine of information on the very subjects about which they are most anxious to obtain trustworthy contemporary statements. The present reprint deserves, therefore, to be cordially welcomed. It has been carefully edited by Miss Betham-Edwards, who, in an interesting introduction, prepares the way for the study of the book by presenting "a contrasted picture of France under the *ancien régime* and under the third Republic." She also gives a valuable biographical sketch of Arthur Young, the materials having been supplied by his grandson.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Acquired Characters and Congenital Variation.

MR. DYER accuses me of invading the pages of NATURE by methods of discussion characteristic of the political debater. Those methods, however, may be good as well as bad. In addition to direct affirmative arguments in support of a particular conclusion, they may trace the working and the power of preconceptions which in science, as well as in other things, are an abounding source of error. On the other hand, methods of debate may be confused and declamatory, dealing in vague phrases, and delighting in clap-trap illustrations. If I could not handle a scientific question by some method less adapted to the "shilling gallery" than the method of my censor in this case, I should wish to be silent for evermore. In his letter I see "Teleology" compared to "a wise damsel" who is "temporarily ruffled," but who nevertheless "gathers up her skirts with dignity." I see Addison brought in, head and shoulders, with "the vision of Mirza." I see Fortuity described as "inseparable from life," with the somewhat obscure oratorical addition that "it is at the bottom one of the most pathetic things about it." I see mixed metaphors of all sorts and kinds, "the church," and "orthodoxy," and "automatically self-regulating machines," and "tenacity about outworks"—and many other such words and phrases—all handled according to methods which do not strike me as at all perfect examples of true scientific reasoning.

Nor am I able to follow Mr. Dyer's logic better than I can admire his declamation. The object of my last letter, which he attacks, was to lay down and defend the proposition that "there is no necessary antagonism between congenital variation and the transmission of acquired characters." Mr. Dyer admits this proposition to be "perfectly reasonable," adding, in respect to this supposed antagonism, "theoretically there is none." But then he proceeds to say, "this does not make the transmission of acquired characters less doubtful." In other words, the complete and effectual removal of an adverse presumption is of no value in an argument which rests altogether on difficulties and doubts. This would be unreasonable enough considered merely in the abstract. But it becomes still more unreasonable when we recollect that the whole doctrine of evolution implies, of necessity, the continual rise of new characters and the transmission of them. These new characters are "acquired" in one sense, and they may be congenital in another. They not only may be, but probably they must be, acquired from latent congenital tendencies, and they may be fixed and transmitted only by those tendencies ceasing to be latent. On this view of the matter, the present controversy between the two conceptions becomes a mere logomachy. The different breeds of dog do undoubtedly transmit characters which have been "acquired." But it is always possible to assert, and always impossible to deny, that these characters arose out of congenital tendencies latent in the species. Mr. Dyer's assertion that this method of reconciling the two ideas "does not make the transmission of acquired characters less doubtful," is an assertion, therefore, which is obviously wrong. The reconciliation attacks the difficulty about the "inheritance of acquired characters" at its very heart and centre. It shows it to lie—as a thousand other difficulties have lain before—in an ambiguous word. "Acquired"? Yes; but from what? From "use"? Yes, but whence came the possibility

of "use"—and the tendency—or the disposition—or the instinct—to use? The answer may be, and perhaps always must be, that the possibility of each new use, and the disposition to it, has been acquired from the evolution of elements inherent in the germ.

The next specimen of pure scientific reasoning which I find in Mr. Dyer's letter is involved in his rebuke to me for having made an assertion in support of which I have produced no "definite observed evidence." That assertion he correctly quotes thus:—"All organs do actually pass through rudimentary stages in which actual use is impossible." He challenges me for proof. I return the challenge, and summon Mr. Dyer to produce one single instance of any animal which does NOT pass through such stages. It is the universal law of all organic beings. In some germ—in some bud—in some egg—in some womb, every living thing begins to grow. Moreover, what is true of it as a whole, is true of all its parts. All its organs—be they few and simple, or many and complex—pass through stages of incipience, of impotence—of divorce from even the possibility of actual and present use. It is truly an astonishing circumstance that any scientific man should ask for any proof of this. It is a signal illustration of the power of neglected elements in reasoning—of the familiar becoming the practically unknown, because it is the unconsidered.

Possibly, Mr. Dyer may say that he did not understand me to make the assertion of each individual organism. But this is a distinction without a difference. If the Darwinian theory be true, there has never been any other origin for species than the origin of a few first germs—developed ever since by the processes of ordinary generation, through a succession of individuals. The well-known generalization of Darwinian embryologists is that the fœtal development of the individual organism is the type and repetition of the development of species in the womb of time. In the doctrine of "prophetic germs," which he quotes as mine, nothing is mine except, perhaps, the adoption of the words. It is the embodiment, in what I hold to be accurate and appropriate language, of the most familiar facts in nature, and of the intellectual conceptions which are their necessary counterpart in mind.

There is one consequence necessarily following from this conception, which is seldom thought of and never fully accepted or recognized; and that is, that, if every organism has been developed from older organisms by very slow and gradual and minute changes through unnumbered ages, there must have been a constant succession of new organs coming on, along with an equally constant succession of other organs passing off. I see no escape from this conclusion. Yet if it be true, nothing can be more unreasonable than to wonder at the occurrence of structures which are divorced from actual use, and which are variously called "rudimentary," or "aborted." The common interpretation always is that they are the inherited remains of structures which have been once in full use, and have been lost by the atrophy of disuse. This may or may not be true, according to special facts in each case. But that there has always been in time past a series of incipient structures on the rise for actual use in future generations of development is a necessary consequence of the Darwinian hypothesis, and indeed of all other forms of pure evolutionism. The only escape from it is the supposition that special organs may have arisen suddenly—may have advanced rapidly into functional use—as rapidly as a caterpillar rushes into the structure of a butterfly, after a short interval of inactivity or sleep.

This is possible—this is at least conceivable. Nay more, this may have been the process by which new species have been introduced. But this is not Darwinism. The occasional introduction of new germs, with new potentialities, and the "hurrying up" of these through rapid stages of development, or of hatching, is an idea which, if I remember right, did not escape the speculative glance of Darwin. But it was too incongruous to be easily assimilated with his special formulæ, and so his fine eye glanced off it again, after only a momentary look; and at a later date he was so biassed in favour of the mechanics of fortuitous variation that he came to regard the very idea of development being guided towards any use yet lying wholly in the future as incompatible with his theory, and indeed destructive of it.

Mr. Dyer says that there was nothing in my last letter "which has not been worn threadbare by discussion." If so, it seems a pity that Mr. Dyer should have interposed in a discussion which he thinks exhausted. This impression may account for the poverty of the contribution made by an able man to a subject which is perhaps the most difficult, the most interesting, and the most far-reaching which can engage the human understanding. ARGYLL.

Inveraray, January 19.

Multiple Resonance obtained with Hertz's Vibrators.

WHILE Mr. Trouton and I were carrying out some experiments to try and drive an independent current through the arc formed when a spark passes in a Hertzian resonating receiver, we succeeded to some extent in doing so, but obtained an unexpected result which may be of service to others working upon this matter. We found that if the two sides of the receiver be connected with a delicate galvanometer, it is affected whenever a spark passes. It is not so easy to get sparks to pass when the galvanometer is so connected as when the receiver is insulated; but whenever a spark passes, the galvanometer—a 7000-ohm Cambridge Scientific Instrument Company's pattern—is deflected through several degrees and often off the scale. It is not very easy to see how the action takes place, because one would imagine that an electro-dynamometer would be required. The current is reversed along with the reversal of the primary induction, and seems to be connected with the direction of the electromagnetic impulse that first breaks down the air-space in the receiver: an explanation founded upon this consideration explains the facts so far, but further investigation is required to fully confirm it. We have found this method of observing the Hertzian phenomena, which we have worked successfully with an apparatus giving a wave-length of 0·6 metre, much more satisfactory than the method founded on utilizing the conductivity of the spark as a path to drive an independent current either across or along. Some experiments in a vacuum tube, however, showed that this method is capable of extension. We found it also more satisfactory than a bolometer method, which, however, worked fairly well. For this we interposed, instead of the spark-gap, a very fine wire, which was made into one of the arms of a Wheatstone's bridge. The great desideratum was a *very* fine wire, and we intend trying silvered quartz fibres if we can obtain them, and lead drawn inside glass, &c., our hearts having been broken trying to use that brittle beauty, Wollaston wire.

Any of these methods, in which your observing apparatus, the galvanometer, can be at a distance from the receiver, is more manageable than ones like that described by Mr. Gregory, in which the receiver is itself also the observing apparatus. We exhibited our method of observing the occurrence of spark by connecting the ends of the spark-gap with a delicate galvanometer at the meeting of the Dublin University Experimental Science Association last November. GEO. FRAS. FITZGERALD.

January 25.

As I see from a notice of the proceedings of the Academy of Sciences, Paris, in last week's NATURE (p. 287), that MM. Edouard Sarasin and Lucien de la Rive have observed the fact that "multiple resonance" can be obtained by using different sized resonators with a Hertzian "vibrator," I adjoin the following short account of experiments of a somewhat different character made during last autumn, which have led to the same results, and which were brought before the notice of the Dublin University Experimental Association last November. Since then I have learnt what these experimenters also seem not to have known—that some of Hertz's earlier experiments were more especially concerned with this very fact.

First, it was found that the wave-length in the Hertzian experiment of loop and nodes formed by reflection from a large metallic sheet had altered since the apparatus had been last used some months previously. This was attributed at first to something in the "vibrator," such as the width of the spark-gap; but ultimately, on remembering how an accident had necessitated a new resonator being made, the cause was recognized—namely, that it was not exactly the same size as the previous one; and when several resonators of different sizes were made, they were found to give the node at different distances from the reflecting sheet. The intensity of the sparking with which these were affected increased with their size up to a certain point, and then diminished. So that it seems as if a "vibrator" did not send out a "line spectrum," so to speak, but sends out a "band spectrum," the centre of which is the brightest. The period, then, of a "vibrator" is that belonging to the centre of this "band."

Again, in like manner, a "resonator" was always found to give the node in different positions according to the size of the "vibrator" employed. This is what would be expected from the principle of resonance, a resonator being able to respond to any member of the "band" it would itself give out when acting as a radiator, the central period of course with the greatest ease. Some such factor as $\epsilon^{-(\lambda-\lambda_0)^{2n}}$ could, perhaps, express this sort of thing, where λ belongs to the period of the radiation, supposed for the moment "monochromatic," falling on the resonator, and λ_0 belongs to the "period" of the resonator, or that of the centre of its "band."

The position of the node was also found to vary on altering the character of the dielectric surrounding the resonator; even laying a piece of sealing-wax on the wire of the resonator was sufficient to be observed. This might be employed to determine "V" in a dielectric of which only a small quantity was obtainable.

It is obviously of importance for the "central period" of the resonator employed to coincide with that of the vibrator, especially when determining the velocity of the disturbance, for this is presumably the period given by theory. This is practically always done when arranging their relative sizes, so as to obtain greatest intensity. So that the caution urged by M. Cornu in connection with Prof. Hertz's measurements of this velocity seems, from these considerations, to be to a great extent unnecessary.

It would obviously be of importance to investigate what form the resonator should take, so as to give out a radiation most approaching one definite period. FRED. T. TROUTON.

Bourdon's Pressure Gauge.

As there does not seem to be in any of the more familiar textbooks of Physics or Engineering any satisfactory explanation of the action of the Bourdon gauge, the following may be of use to some of your readers.

What we have to explain is the uncurling of the gauge under internal pressure whether of gas or liquid.

Instead of the usual flattened tube of more or less elliptical section

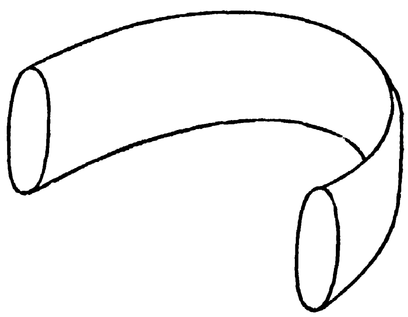

FIG. 1.

bent into the arc of a circle as in Fig. 1, think, for convenience, of one of rectangular section, such as AB of Fig. 2, in which A

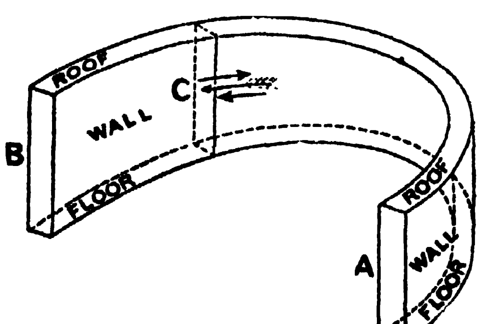

FIG. 2.

is the fixed and B the free end, and in which we shall distinguish, as indicated, the walls, roof, and floor.

If the annulus of tube were complete, as shown in the central cross-section (Fig. 3), then it is evident that under the influence of internal fluid pressure the outer wall would be everywhere in a state of tension in the direction of its length, and the inner wall in a state of compression. In the immediate neighbourhood of the ends A and B this state of compression or extension will be somewhat modified, but at a sufficient distance from either the condition of the walls will be the same as if the annulus really were complete.

If T be the tension of the outer wall in the direction of its length, P the pressure of the inner, and R the resultant fluid pressure on any cross-section such as A or B (Fig. 2), then for the equilibrium of the half of the annulus lying on either side of the diameter AB (Fig. 3) we must have

$$T = P + R.$$

Consider now the equilibrium of any portion BC (Fig. 2) contained between the free end B and a cross-section C at some little distance from B, when the internal pressure is applied, and before uncurling takes place.

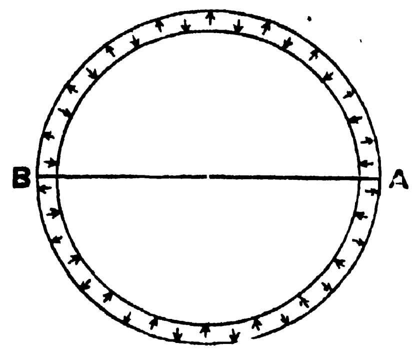

FIG. 3.

Imagine the fluid within BC to be solidified, then the external forces acting on BC (see Fig. 4) reduce to

(1) A tension, T, due to the action of the outer wall beyond C.
(2) A pressure, P, " " inner " "
(3) A resultant fluid pressure, R, acting at the centre of pressure of the cross-section C.

and since P + R = T, these reduce to a couple tending to uncurl the tube, and the same holds for all sections sufficiently removed from A and B.

As the tube uncurls, however, new forces come into play, viz. the resistance to bending of the walls, but especially of the floor and roof of the tube, whose width in the direction of a principal

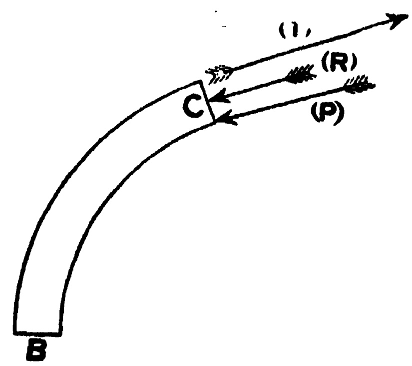

FIG. 4.

radius of the annulus, and consequently whose resistance to bending, is much greater than that of the walls. Uncurling goes on till the moment of the couple resisting flexure is equal to the moment of the bending couple.

It is evident from this explanation that even a tube of circular section would tend to uncurl, but that it would be very insensitive on account of its strength to resist flexure, and that up to a certain point sensitiveness is gained by having the walls of thin material, high, and very near together.

Devonport, December 23, 1889. A. M. WORTHINGTON.

Foreign Substances attached to Crabs.

REFERRING to Mr. F. P. Pascoe's letter (NATURE, December 26, p. 176), I cannot refrain from expressing my astonishment at his inability to "see where protection comes in" in the case of crabs covered with sponges, Polyzoa, &c. I should have thought it obvious to everybody that slow-moving crabs, such as all those he mentions and many others that I have seen, would have a much better chance of escaping their enemies when

covered with material that renders them almost indistinguishable from the stones and gravel in which they are found than if they were naked.

As regards the use of the peculiar hind legs in the Anomoura and *Dorippe*, perhaps the enclosed extract from a paper read by me on December 12 before the Chester Society of Natural Science may be of interest. It will shortly be published in vol. iv. of the Transactions of the Liverpool Biological Society.

ALFRED O. WALKER.

London, W., January 17.

"An interesting fact, illustrating the ingenuity shown by more than one species of Crustacea in concealing themselves, came under my notice last summer. Having dredged a number of Amphipoda, I placed them in a vessel of sea water till I could examine them. Among them I noticed what seemed to be a piece of dead weed swimming rapidly about and occasionally falling to the bottom. Examination with a lens showed that the piece of weed was carried by an Amphipod (*Atylus swammerdamii*), which grasped it by the two first pairs of walking legs (peræopoda). When it came to the bottom the animal concealed itself beneath the weed, which was much larger than itself.

"In connection with this habit of *A. swammerdamii*, it may be mentioned that another species, *Atylus falcatus* (Metzger), resembles the first-named minutely in every respect but one, viz. that the first peræopod has the claw (dactylus) immensely developed, while at the base of the next joint are two or three strong blunt spines or tubercles into which the point of the claw fits. This would appear to give the latter species a great advantage over its congener in grasping an object for purposes of concealment. It is a rare species, but I have met with a few specimens this summer: I am not aware of its having been recorded as British yet.

"In some of the Podophthalmata the same instinct has been observed, and especially among the Anomoura. All these have the last or hindmost pair of legs of a shrunken and apparently almost abortive form. They never appear to be used for walking, and are generally carried turned up on the back; but they are utilized by some species of curiously shaped, flat-bodied crabs (*Dorippe*) to carry the valve of a bivalve mollusk over their backs, under which they can squat and hide. From this it is an easy transition through various stages to the hermit crabs (*Paguridæ*), which ensconce themselves altogether in a univalve shell, and use the curiously abortive hind limbs to cling to the inside whorls. My friend Surgeon-Major Archer has seen crabs of the genus *Dorippe* protecting themselves (probably from the scorching tropical sun), at low tide, on the mud flats at Singapore, by carrying large leaves over their backs (Journal of Linn. Soc., vol. xx. p. 108)."

I CAN corroborate Mr. Ernest Weiss's remarks on the use of the modified legs of Dromia. A small one I had in an aquarium would, when the sponge was removed from the back, hunt about until it found something—a shell, a pebble, or even a dead fish—to replace the sponge. When there was nothing in the aquarium which it could seize, it was evidently in an unhappy condition.

With regard to foreign substances on other crabs, I have caught spider-crabs so completely covered with sponges as quite to hide their shape, and, until they moved, it was impossible to say what they were.

DAVID WILSON-BARKER.

Thought and Breathing.

WITH reference to Prof. Leumann's researches into the influence of blood circulation and breathing on mind life, referred to in NATURE of January 2 (p. 209), it is worthy of note that regulation and suppression of the breath (*Prānāyāma* or *Hatha-Vidyā*), is an all-important religious observance amongst Hindus.

It is one of the eight chief requisites of the Yoga philosophy, for attaining "complete abstraction or isolation of the soul in its own essence," and minute instructions exist for the exercise, which is adopted, apparently, as an immediate aid to deep meditation. Some of these instructions are quoted in Prof. Monier-Williams's recent work on Buddhism (p. 242), and he also quotes, in connection with this subject (p. 241), Swedenborg's opinion that thought commences and corresponds with respiration.

Swedenborg also says:—"It is strange that this correspondence between the states of the brain or mind and the lungs has not been admitted in science."

R. BARRETT POPE.

Brighton.

On the Effect of Oil on Disturbed Water.

HAVING seen the interesting article by Mr. R. Beynon on the above subject (NATURE, January 2, p. 205), shortly before leaving England, I propose to make a few observations on the theoretical aspect of the phenomena described by him.

The simplest case of wave-motion in a viscous liquid arises when two-dimensional waves are propagated in a liquid whose depth is so great in comparison with the lengths of the waves that the former may be treated as infinite. If at any particular epoch, which we may choose as the origin of the time, the form of the free surface is determined by the equation $\eta = A\epsilon^{\iota mx}$, where $2\pi/m$ is the wave-length, its form at any subsequent time may be represented by $\eta = A\epsilon^{kt+\iota mx}$, and the object of a theoretical solution is to find the value of k. The equation for determining k is given in the last chapter of my "Hydrodynamics"; and it is there shown that if the viscosity of the liquid be sufficiently small, k will be of the form $-\alpha \pm \iota\beta$, where α and β are *real positive* constants. Hence the equation of the free surface, in real quantities, may be written—

$$\eta = A\epsilon^{-\alpha t}\cos(mx - \beta t) \quad . \quad . \quad . \quad . \quad . \quad (1)$$

which represents periodic motion whose amplitude diminishes with the time, and which therefore ultimately dies away, the rapidity with which the motion decays depending upon the magnitude of α. If, however, the viscosity be large, the solution changes its character, since in this case k is a *real negative* quantity, and the equation of the free surface becomes

$$\eta = A\epsilon^{-\alpha t}\cos mx \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

which represents non-periodic motion, which rapidly dies away.

The phenomena discussed by Mr. Beynon are somewhat different from the special case of deep-sea waves, inasmuch as a thin film of a highly viscous liquid, viz. oil, whose thickness is very small compared with the wave-length, is spread over the surface of water, which is a liquid whose viscosity is so small, that it might probably be neglected altogether. The action of the wind would also introduce an additional complication; but the circumstance that the thickness of the oil is small compared with the wave-length, would, on the other hand, facilitate the calculations which would be necessary in order to obtain a theoretical solution. There can, however, I think, be little doubt that the free surface would be given by equations of the forms either of (1) or (2); where α is so large, that after a short time has elapsed after the film of oil has spread itself over the water, the amplitude of the existing motion would be small compared with that of the original motion.

A. B. BASSET.

Hôtel Beau Site, Cannes, January 11.

Luminous Clouds.

IN the correspondence that has taken place on luminous clouds, totally different classes of phenomena have been mentioned. There are *self-luminous* clouds entirely distinct from what I have termed "sky-coloured clouds," which latter, though by some deemed self-luminous, have been generally admitted to shine by reflecting the direct light of the sun.

The self-luminous clouds described by Mr. C. E. Stromeyer (p. 225) appear to have been a part of the aurora which was visible at the same time; but other correspondents have mentioned self-luminous clouds which have apparently not been of a truly auroral character, and the nature of these clouds seems not to be understood, and requires investigation; there may be various kinds of these and causes of their luminosity. I have myself not unfrequently seen what I call *irregular auroras*, which may be one form of what others call self-luminous clouds. They consist of bands which, unlike regular auroras, appear indifferently in all parts of the sky, and lie in any direction; they are usually much fainter than the Milky Way, and are always feebler near the zenith than near the horizon. The bands composing them are generally parallel, or nearly so, and 3° to 10° wide. They differ from ordinary cirrus in being, so far as I can judge, perfectly transparent, and also in moving extremely slowly, giving one the impression that they are much higher up in the atmosphere than cirrus. Their spectrum is

continuous, though they are sometimes as bright as true magnetic auroras which show the citron line.

The average number of nights on which I have seen these irregular auroras in the past 28 years, chiefly at Sunderland, is 1·9 per annum; and, if doubtful cases are included, 2·7. They agree with magnetic auroras in so far as they show some tendency to an eleven-year periodicity, being most frequent about 2 years after the sun-spot maximum, and least so about 5 years later. T. W. BACKHOUSE.

Sunderland, January 15.

MR. STROMEYER's letter in NATURE of the 9th inst. (p. 225) reminds me of a magnificent display that I once saw of luminous white clouds, transparent to the stars, which shone brightly through them. These clouds were extended like ribbons from north to south across the sky, in a way not uncommon with true clouds. I thought, and still think, that they were an aurora. May not those described by Mr. Stromeyer have been the same?

Belfast, January 15. JOSEPH JOHN MURPHY.

The Meteorite of Mighei.

WITH reference to the interesting meteorite of Mighei, examined by M. Stanislas Meunier, I have not observed, in any of the notices I have seen, any statement as to whether the organic matter exhibited any traces of an organized structure. I would suggest that, if it has not already been done, it should be carefully examined to see if the carbonaceous matter shows any such traces. J. RUTHERFORD HILL.

January 11.

Achlya.

I SHALL be very grateful to any of your readers who can send me specimens of *Achlya* with the sexual reproduction, which I cannot at present obtain in my cultures. The culture should be dropped bodily into a cold saturated solution of corrosive sublimate, in a wide-mouthed corked bottle, and this filled up with the liquid to the cork before posting.

MARCUS M. HARTOG.

5 Roseneath Villas, Cork, January 6.

The Parallelogram of Forces.

WHAT is the force of the word "rigid," introduced into the statement and proof of the parallelogram of forces and other theorems in Statics, as quoted by Mr. W. E. Johnson from the ordinary text-books?

The word "rigid" requires definition; it describes a state of things which is not met with in Nature; and it is redundant and limiting; because the conditions of equilibrium of a body are the same, whether elastic to an appreciable extent, or to such an inappreciable extent that the word "rigid" may be applied to it.

Better omit the word "rigid" altogether.

A. G. GREENHILL.

Foot-Pounds.

IN the statics and dynamics paper set in the last Woolwich entrance examination, candidates are asked to determine the magnitude of a moment of a force in *foot-pounds*. Surely it is unfortunate to introduce this term in such a sense. One foot-pound is a unit of work, and though its dimensions (ML^2T^{-2}) are the same as that of a unit of a moment of a force, the two conceptions are perfectly distinct, and the introduction of a foot-pound as a unit of a moment of a force is likely to cause confusion, especially in the minds of beginners.

A. S. E.

Chiff-Chaff singing in September.

IN a review of certain recent ornithological works, in one of your latest issues, doubt seems to be thrown on the fact of the chiff-chaff singing late in September.

I believe it is not an unusual occurrence. It always nests in my garden, and this year, as I see by a note made at the time, it sang on the 20th, 21st, and 22nd of that month. We had a slight frost on the 21st. F. M. BURTON.

Highfield, Gainsborough, January 6.

EAST AFRICA AND ITS BIG GAME.[1]

FOR sporting purposes Cape Colony and the adjoining districts are long ago "used up," and the hunter who would fain see "big game" must follow Mr. Selous into Matabelé-Land and Mashoona-Land, if he does not find it better to cross the Zambesi. Even here, some of the largest animals are already exterminated. The redoubted hunter whose name we have just mentioned has not met with a White Rhinoceros during the past four seasons, and his "bag" of ivory shows a yearly diminution. So much for the south of the Dark Continent. The northern entrance to the great Interior, which afforded Sir Samuel Baker and those who followed him such splendid sport on the Atbara and Settite, has been closed up by the Mahdists, and until we have made up our minds to "clear out Khartoum," no European can hope to penetrate in this direction. There remains, therefore, only the eastern coast as a mode of access to the wild interior of game-tenanted Æthiopia, the west coast being practically closed by swamps and fevers.

On the eastern coast of Africa, however, immediately under the equator, a splendid stretch of high-lying land, full of big game, and easy of access, is still open to the enterprising sportsman. First made known to us by the German missionaries Rebmann and Krapf, the "Kilimanjaro District," as it is now usually called, was subsequently opened to us by Von der Decken, New, and Hildebrandt. To these explorers succeeded Mr. Joseph Thomson on his route to Masai-Land, and Mr. H. H. Johnston on his expedition up the Kilimanjaro Mountain, to which Dr. Hans Meyer and other more recent travellers have also devoted their special attention. Access to this sportsman's paradise is rendered easy by the port of Mombas, now under the benign sway of the British Imperial East African Company, and connected with Aden by a regular line of steamboats. Here, in the autumn of 1886, having made the necessary preparations at Zanzibar, the author of the present volume, with his brother sportsmen Sir Robert Harvey and Mr. H. C. V. Hunter, assembled their caravan. Their plan was to reach as quickly as possible the forest of Taveta, distant about 250 miles from the coast and within ten miles of the base of Kilimanjaro, and having established their head-quarters in this favoured spot, to work thence the surrounding plains and open country. Mr. C. B. Harvey, the brother of Sir Robert, was to join them when his leave commenced, a month later.

How well this programme was carried out the entertaining pages of Sir John Willoughby's narrative fully explain to us, while the map at the commencement clearly shows the route and the nature of the different districts traversed, as they appeared to the eyes of the enthusiastic sportsmen. Much time and trouble was saved to the expedition by the selection of a Maltese named Martin as "chief of the staff." Martin had accompanied Mr. Thomson during his adventurous journey into Masai-Land, and was, moreover, the owner of a "freehold building-site" at Taveta. Hereon was a house and a range of huts, forming three sides of a large square, while the fourth was bounded by a sparkling rivulet well stocked with fish. Such a haven of refuge, protected, as it was, by a thorn-hedge with a strong gateway, and situated in the immediate vicinity of a good game-country at an elevation of 2400 feet above the sea-level, seemed little less than a Paradise to our travellers, who arrived here on December 26, about sixteen days after leaving Mombas. Into their various excursions from this convenient centre we need not closely follow them. Suffice it to say that their routes were

[1] "East Africa and its Big Game, the Narrative of a Sporting Trip from Zanzibar to the Borders of the Masai." By Captain Sir John C. Willoughby, Bart., Royal Horse Guards. With Postscript by Sir Robert G. Harvey, Bart. Illustrated by G. D. Giles and Mrs. Gordon Blake; those of the latter from photographs taken by the Author. (London: Longmans, 1889.)

mostly to the west of Taveta, amongst the numerous streams that drain the southern slopes of Kilimanjaro and unite to form the Ruvu River, which enters the sea at Pangani, and to the east of the great mountain on the head waters of the Tzavo. These various hunting expeditions occupied the time until April 21, when a safe return was effected to Mombas, and thence to Europe.

The list of larger game-animals killed by the party during their four months shows a goodly total of 330 head, although we are assured by Sir John Willoughby that no useless slaughter was perpetrated during the expedition, and that no animal was killed unless required for a specimen, or for food by the hunters and their native companions. In the list of these 330 animals, we find 21 Buffaloes, 66 Rhinoceroses, 2 Elephants, 4 Hippopotamuses, 4 Zebras, and 211 Antelopes of different species.

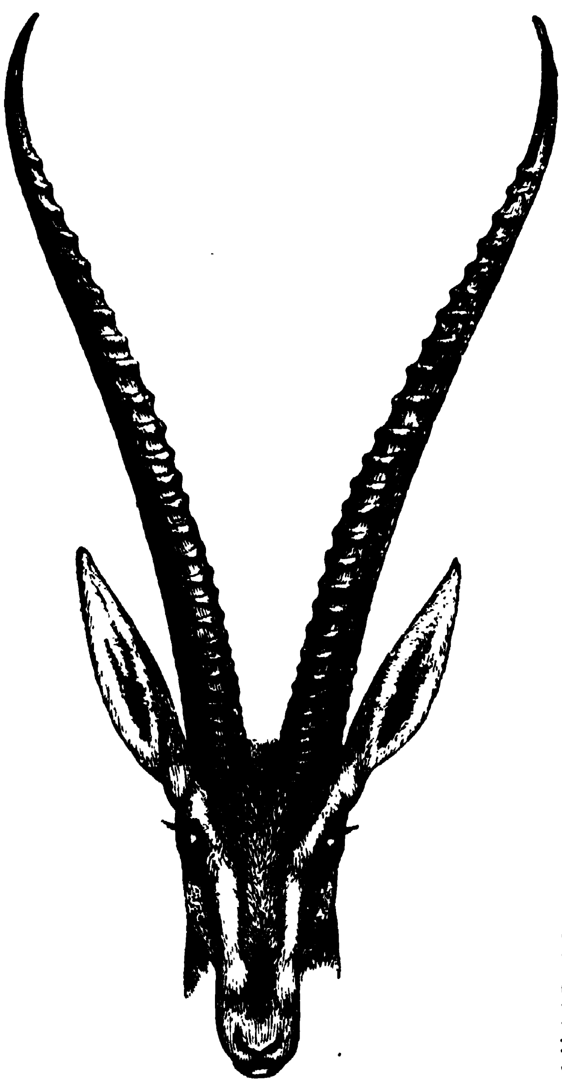

FIG. 1.—Head of Grant's Gazelle.

But a much more attractive list to the naturalist will be found in the appendix "on the fauna of the plains round Kilimanjaro," compiled by Mr. Hunter. So little is yet known of the larger mammals of this fine country, except from fragmentary notices, that Mr. Hunter's notes, brief as they are, form a not unimportant contribution to zoological science. Lions, Elephants, Hippopotamuses, and Giraffes are prevalent alike in every part of Wild Africa, but the splendid Bovine animals called Antelopes vary very materially in the different districts. In the Kilimanjaro country, sixteen Antelopes are recorded as having been met with, and amongst them are some of the finest and largest of the whole group. The Eland (*Oreas canna*) is "rather local," but there "are a fair number to the south of the mountain." The Eland found here belongs to the variety called Livingstone's Eland, first met with by that great explorer on the Zambesi. "Both males and females are all more or less striped." The Larger Kudu (*Strepsiceros kudu*) was "only seen on two or three occasions on the Useri River"; the Lesser Kudu (*S. imberbis*) is found "in the bush around Taveta," and in several other localities. Two examples of this until lately little-known Antelope from this district are now living in the Zoological Society's Gardens. The Beisa (*Oryx beisa*) is "plentiful on the plains and in thin thorny bush"; the Coke's Hartebeest (*Alcelaphus cokii*) is "quite the most common Antelope on the plains, being found everywhere in immense herds"; while the Brindled Gnu (*Connochætes gnu*), the Mpallah (*Æpyceros melampus*), and the Waterbuck (*Cobus ellipsiprymnus*) are, according to Mr. Hunter, abundant in appropriate localities. We suspect, however, that Mr. Hunter's so-called "Waterbuck" is the Sing-sing (*Cobus sing-sing*), of which some fine heads were procured by Mr. Holmwood, lately H.B.M. Consul at Zanzibar, during an excursion to the Tavita district. Of the beautiful tribe of Gazelles, three well-marked species, all recently discovered and appropriately named after distinguished African travellers, tenant the plains of Kilimanjaro. These are the Grant's Gazelle (*Gazella granti*), the Thomson's Gazelle (*G. thomsoni*), and the Waller's Gazelle (*G. walleri*). Grant's Gazelle is "common everywhere on the open plains." Its fine lyre-shaped horns attain a larger development than in perhaps any other species of the genus. Their elegant shape and prominent outlines will be seen by the accompanying figure from the Proceedings of the Zoological Society. Thomson's Gazelle was found in large numbers in the plains of the Masai country to the south-west of the mountain.

FIG. 2.—Head of Hunter's Antelope.

Waller's Gazelle was "very rare near Kilimanjaro," but subsequently found to be numerous up the Tana River. One was killed near Lake Jipé. But the great prize among the Antelopes was met with by Sir Robert Harvey and his companions Messrs. Greenfield and Hunter, during a subsequent expedition to Eastern Africa. In the course of this journey they ascended the River Tana, which forms the northern boundary of the dominions of the British Imperial East African Company. Here, on the northern bank, they came across specimens of an entirely new Antelope, "of a bright red colour, in some respects resembling a Hartebeest, especially in regard to the length of its head, and of about the same size, but hardly so high at the withers." This

Antelope has been since named Hunter's Antelope (*Damalis hunteri*) by Mr. Sclater (see Proc. Zool. Soc., 1879, p. 372, Pl. xlii.), and mounted specimens of it may be seen in the Mammal Gallery of the Natural History Museum at South Kensington.

It must not, however, be supposed that the rich mammal-fauna of the Kilimanjaro district has been yet entirely exhausted. We read, in Sir John Willoughby's narrative, of a Duiker Antelope (*Cephalophus*), of a dark red colour, found on the mountain, of which a specimen was obtained by an American traveller, Dr. Abbott, but not by the British sportsmen. On the same mountain, at an elevation of about 9000 feet, Dr. Abbott also secured an example of an "extraordinary animal" like a Serow (*i.e. Capricornis bubalina* of the Himalayas), but "darker in colour and shorter on the legs." There is therefore ample room for future discoveries, both in this and in other branches of natural history. The plateau surrounding Mount Kenia, which has yet to be explored scientifically, would doubtless supply many other novelties. In short, at the present time we know of no other field for zoological discovery so promising and so easily accessible as the slice of Eastern Africa recently assigned to Sir William Mackinnon and his associates of the B.I.E.A. Company, to which the author of the present volume has given us such a useful and agreeable introduction.

THE CORAL REEFS OF THE JAVA SEA AND ITS VICINITY.[1]

SINCE comparatively few of the naturalists who have sojourned in the Indian Archipelago have paid special attention to the coral reefs of that region, it becomes a cause of satisfaction that Dr. C. Ph. Sluiter, of Batavia, who has long been engaged in studying the marine fauna of his neighbourhood, has taken up the subject in earnest. In a paper on the origin of the coral reefs of the Java Sea, and of Brandewijns Bay on the west coast of Sumatra, and on the new coral formations of Krakatão, Dr. Sluiter gives the results of his recent preliminary investigations.[2] This paper is excellent in method, and the results of the highest importance.

In the western half of Batavia Bay, where the depth varies from 5–12 fathoms, there are numerous coral reefs which occur in all stages of growth from the incipient reef to the coral island begirt with a barrier-reef. Being curious to learn how the corals first began to grow on the muddy bottom of this bay, the author of this paper soon found an explanation in the fact that the stones and fragments of sunken Krakatão pumice, which lay in places on the mud, were covered with living corals. Hence he concluded that in those favourable circumstances where several of the stones and pumice fragments lay close together we might have the beginning of a reef. A singular feature in the growth of these reefs then attracted his attention. Some fourteen years ago, an artesian boring was made in the small coral island of Onrust in Batavia Bay, when an accumulation, 20 metres thick, of coral *débris*, shells, and clay, was found to pass downward into a firmer clay. The depth of the sea around is only 11 metres, and after allowing about 2 metres for the height of the island, Dr. Sluiter infers that the coral fragments have sunk down 7 metres into the mud or clay of the sea-bottom.

To support this view, the author gives a section of the shore-reef of Brandewijns Bay, on the west coast of Sumatra, the section being constructed from data supplied by fifteen borings, none deeper than 24 metres, the reef there being rather under 300 metres wide. As is there shown, the volcanic formations of the steep coast-border descend at a precipitous angle under the sea, so that they do not form a foundation for the shore-reef. This reef, the thickness of which varies greatly, being in some places as much as 11 metres and in others only half that amount, lies on "a substratum of clay or mud mixed with coral *débris*, and forming a bed ranging from 2 to 7 metres in thickness." This substratum of clay and coral passes down into a clay or mud, formed from the decomposed andesitic rocks of the district, which may be firm in some places and soft in others. The next point brought out in the section is that the substratum of clay and coral *débris* is thickest and deepest where the underlying clay is soft, and thinnest and nearest to the surface when the clay is firm or is mixed with sand. From these and allied considerations, Dr. Sluiter passes on to the conclusion that the same process has taken place here which occurs in the construction of dams and piers on a yielding bottom, a large amount of coral materials having been sunk in the mud, whilst the reef, by its own weight, has prepared its own foundation.

Having been familiar with the appearance of Krakatão before the great eruption of 1883, Dr. Sluiter observed some interesting changes in connection with the shore-reefs of this island when he revisited it in 1888 and 1889. The pumice and ashes at the time of the outbreak, according to the account of Dr. Verbeek, the historian of the eruption, destroyed all life in the sea around, making the sea-bottom a lifeless waste; and under an accumulation, 20 metres thick, of these materials lies the old shore-reef. In 1888 and 1889 the old condition of things was beginning to re-assert itself. In one place a young shore-reef, composed mostly of madrepores, had attained a breadth of a metre, and living corals were brought up in abundance by the dredge, attached to sunken pumice. Amongst the measurements of coral growth given by the author are those relating to specimens of *Madrepora nobilis*, Dana, which had attained a length of from 2 to 2½ decimetres in a period that could not have exceeded five or six years, and was probably much less. Specimens of *Porites mucronata*, Dana, had also in the same period grown to a length of 1 decimetre.

After referring briefly to the interesting Thousand Islands, a linear group of small coral islands near Batavia, many of which, in the southern part, affect the atoll form, Dr. Sluiter sums up the results of his observations. A coral reef in the Java Sea *commences its growth on a muddy bottom* in the form of a colony of corals growing on the *stones* and *sunken pumice* that there lie. As it increases in extent and height, it secures its own foundation by its weight, a large amount of coral materials sinking into the mud to a depth of seven or less metres. In its upward growth it presents a level top, and displays no hollow or basin, a uniformity which it preserves until a foot from the surface, when it dies in the centre, and the agencies dwelt upon by Murray and Agassiz then co-operate in forming an atoll or a barrier-reef. Because the small coral reefs (500 metres wide) of the Java Sea grow up uniformly until near the surface, Dr. Sluiter places himself in partial antagonism to a portion of Murray's theory. In this, however, he has missed the point of the new view, according to which such small reefs would either have no lagoon or else possess a very shallow one. With this correction, his partial confirmation of Murray's theory becomes more complete.

We hope that, with the great facilities at his disposal, Dr. Sluiter will make an exhaustive examination of the Thousand Islands, the varied and unusual conditions of their growth rendering them particularly important as a field for thoroughly investigating the problem.

H. B. GUPPY.

THE ELECTRIC LIGHT AT THE BRITISH MUSEUM.

THE authorities of the British Museum are to be congratulated on the thorough and admirable manner in which the scheme for the electric lighting of the galleries has been carried out. Everyone present at the private view on Tuesday evening was pleased with the results which had been achieved. Both arc and glow lamps are employed; the former in the galleries on the ground floor containing Greek and Roman sculpture, the Elgin marbles, and Assyrian and other antiquities, and in some galleries on the upper floor. The suite of bronze and vase rooms on the west, and the ethnographical gallery on the east, of the upper floor are lighted by glow lamps. The light from glow lamps is more agreeable to the eyes than the more powerful light of arc illuminants; but these have been regulated with the utmost care, and on Tuesday evening there was a very general feeling that the beauties of the sculpture were brought out by them more effectually than by such daylight as is at times rendered possible by our northern climate. With regard to the arc lights on the upper floor, it was noticed that they were admirably adapted for the exhibition of the Japanese drawings, even the minutest details of these delicately finished works being rendered plainly visible without any diminution of the beauty of the colours.

We quote from the *Times* of January 29 the following description:—

"In the galleries on the ground floor there are 69 arc lamps of various powers, while on the upper floor there are 57 arc and 627 glow lamps. In addition to these there are five large arc lamps in the reading-room, six in the court-yard, and upwards of 200 glow lamps in the offices and passages. The total current required to work the whole of the lamps is nearly 1200 amperes, with an E.M.F. of 115 volts at the lamp terminals; and this output is produced by the expenditure of nearly 200 brake-horse-power. The current is generated by four Siemens dynamo machines, each capable of giving an output of 450 amperes and 130 volts, which are connected to a general switchboard in the engine-room by means of which they can be put to work in parallel to any or all of the circuits. The switchboard is fitted with instruments indicating the current given off by each dynamo and four circuits are led from it round the Museum—two for the upper and two for the lower floor. The main wires are laid outside the building. In order to insure safety, and to guard, as far as possible, against failure of light, the motive power is in duplicate. The four dynamos are driven in pairs, each pair by a separate engine with a separate countershaft. Each engine has a separate steampipe in direct communication with the boilers, and there is an ample reserve of boiler power The power of the engines and dynamos is so adjusted that each of the two sets is capable of working the whole of the lamps in those galleries proposed to be lighted on any one evening; the other set standing by ready to work. Further, in order to work if required, at half-power, or in order to provide half-light for the whole of the galleries—which light should suffice for an emergency such as sudden fog or accident—the lamps are connected in pairs alternately, so that half of the number being cut off, the light of the other half still remains evenly distributed. The engines have been supplied and erected by Messrs. Marshall, Sons, and Co. (Limited), of Gainsborough, and the electrical work has been executed by Messrs. Siemens Brothers and Co. (Limited)."

The eastern and western portions of the Museum will be open to the public on alternate week-day evenings, and all the world agrees with the *Times* that "the educational value of the unique collections of art and scientific treasures the Museum contains will be greatly enhanced by the change."

NOTES.

THE Medals and Funds to be given at the anniversary meeting of the Geological Society on February 21 have been awarded by the Council as follows: the Wollaston Medal to Prof. William Crawford Williamson, F.R.S.; the Murchison Medal to Prof. Edward Hull, F.R.S.; and the Lyell Medal to Prof. Thomas Rupert Jones, F.R.S.; the balance of the Wollaston Fund to Mr. W. E. A. Ussher, of the Geological Survey of England; that of the Murchison Fund to Mr. Edward Wethered; that of the Lyell Fund to Mr. C. Davies Sherborn; and a portion of the Barlow-Jameson Fund to Mr. William Jerome Harrison.

THE Council of the Royal Meteorological Society have arranged to hold at 25 Great George Street, Westminster, on March 18 to 21 next, an Exhibition of Instruments and Photographs illustrating the application of photography to meteorology. The Exhibition Committee invite co-operation, as they are anxious to obtain as large a collection as possible. They will also be glad to show any new meteorological instruments or apparatus invented, or first constructed, since last March; as well as photographs and drawings possessing meteorological interest. Anyone willing to co-operate in the proposed Exhibition should furnish the assistant secretary (not later than February 12) with a list of the articles he will be able to contribute and an estimate of the space they will require.

THE second course of the Gifford Lectures at Glasgow will begin on February 5. As announced in the first course, these lectures will treat of what Prof. Max Müller calls "Physical Religion," or the belief in natural, sub-natural, and super-natural powers, discovered in some of the great phenomena of Nature.

SOME most interesting notes on the last days of Father Perry are contributed to the *Tablet* of January 25 by Father Strickland, S.J. The facts stated by the writer bring out in a very striking light the earnest and resolute spirit in which, to the end of his life, Father Perry devoted himself to science. During the voyage he suffered badly from sea-sickness, and on his arrival at the Isles de Salût he was "much done up." Nevertheless, he allowed himself no rest, but landed at once to view the site and introduce himself to the authorities. Captain Atkinson urged him to live on board the *Comus* and land each morning for his work; and Father Strickland is of opinion that if he had done this "his life would not have been sacrificed to his over-anxious desire to do everything for the best for the success of the work confided to him." He preferred, however, to take up his quarters in the hospital, and said nothing about the fact that he was in bad health, making "light of all his personal wants for fear of giving trouble to others." The observatory erected for the occasion was half a mile from the hospital, and "the intervening ground was very rough, being a steep descent and ascent, and the distance was gone over on foot four times each day in fair weather or foul." "On the Friday before the eclipse Father Perry complained of being 'very bad inside,' but he worked on until nearly 3 a.m., and when the men retired to the *Comus* he tried to snatch a little rest where he was, and lay down in a hammock in the tent. He was up again before 6 o'clock to take the position of the sun at rising. At 6.45 the men arrived from the ship, and at 7.30 there was a complete, most careful, and most successful rehearsal of all the operations and duties which were to be performed next morning in the solemn moments of the eclipse, for which they had been preparing so long and had travelled so far. Everyone was surprised at Father Perry's exactitude in contributing to carry out his own orders and his courage in facing fatigue. His readiness to sacrifice himself and his own convenience in order to save trouble to others endeared him to all who worked with him, and challenged their utmost efforts to secure success for their work in

spite of the oppressive climate and surroundings. Just before noon on Saturday, Lieutenant Thierns went to see him at the hospital and found him much exhausted; but he was again at his post in the observatory at 3 p.m., at which time an important photograph was secured with the mirror. In the evening he went on board the *Comus* for dinner, but was only able to lie on a sofa all the time; and he sent to the doctor for some chlorodyne. Much against the wishes and earnest advice of Captain Atkinson (who spoke to me of Father Perry with the sincerest regard and esteem), Father Perry made his way on shore in a violent pouring rain to sleep in his own quarters, and would allow no one to hinder him. Next morning, Sunday the 22nd, was the important moment of the eclipse. Lieutenant Thierns landed with his observatory party at six o'clock, and on arrival was informed by Mr. Rooney that Father Perry had passed a very bad night and was very ill, so a man was sent to help him over the bad half mile from his quarters, as he declined to let himself be carried on a stretcher. He reached the observatory in good time, though in a very exhausted state. As the important moment approached, he seemed to rally, and, during the minutes of the eclipse, seemed to be himself again, and showed no signs of illness or exhaustion. There were two photographic instruments in use—one an old one, which had often been in use before, the other was the special new corona graphic instrument prepared for the occasion, of which Father Perry himself took charge. He was so alert and self-possessed during the eclipse, that his friends about him hoped he was not so ill, but he gave way immediately after, and with much difficulty reached his quarters in the hospital. It was known after, that during the previous night he had been very seriously ill." On Sunday night it became evident that he was suffering from the very worst form of dysentery. On Wednesday, Christmas Day, he was better, and the vessel started for Demerara. All hope was gone on Friday at 1.30 p.m. At 3 p.m. his mind began to wander, and at 4.20 he died. It is pathetic to read that before he quite lost consciousness he thought himself again engaged in "the supreme moment of the scientific mission which had so long filled his thoughts," and "began to give his orders as during the short minutes of the eclipse."

At its annual sitting, the Russian Academy of Sciences elected the following as Corresponding Members:—In Mathematics, Prof. Sophie Kovalevskaya, Stockholm; in Astronomy, Prof. Moris Lœwy, Paris; in Chemistry, Prof. Stanislas Cannizaro, Rome; in Biology, Th. Keppen, Russia, and Prof. Henri Baillon, Paris.

The Sanitary Institute has made arrangements for the ninth course of lectures and demonstrations for sanitary officers. They will be given in the Parkes Museum, and will be specially adapted for candidates preparing for the Institute's examination for inspectors of nuisances. The introductory lecture will be delivered on February 18 by Mr. E. C. Robins. Among the lecturers will be Sir Douglas Galton and Prof. W. H. Corfield. The former will lecture on ventilation, measurement of cubic space, &c; the latter on sanitary appliances.

Messrs. Macmillan and Co. are issuing a monograph of the British Cicadæ, by George Bowdler Buckton, F.R.S. It will consist of eight quarterly parts, each containing on an average ten litho-chromo plates and letterpress, illustrating the forms, metamorphoses, general anatomy, and the chief details connected with the life-history of this family of insects. The work will contain also short diagnoses of all the British species, about 230 in number, most of which have come under the author's notice, each species being illustrated by one or more coloured drawings. Some account will be given of the curious myths and tales told by ancient Greek and Latin poets, and descriptions will be appended relating to the curious sound-organs possessed by some species, and other subjects connected with the economy of this interesting but difficult group of Rhynchotous insects.

Messrs. Macmillan and Co. have in the press a "Manual of Public Health," by Mr. Wynter Blyth, M.R.C.S., Medical Officer of Health for St. Marylebone.

Malta has suffered a great loss in the almost sudden death of Dr. Gulia, Professor of Botany, Hygiene, and Forensic Medicine in the Royal University of Valletta. He was born, in 1835, at Cospicua, a suburb of Valletta, where his father was a physician. He graduated in medicine and surgery, in 1855, at Valletta, and afterwards went to complete his studies at Paris, where he made the acquaintance of a large number of eminent men, including Milne-Edwards, Blanchard, and Vidal. On his return to reside in his native town, he was elected to the above-mentioned Chair in the University in Valletta. Besides attending to his professorial duties and the requirements of a large medical practice, Prof. Gulia found time to edit an important medical journal, in which he exhibited great literary and scientific talents. He also issued, among other writings, a "Flora of Malta." His son is about to publish his last work, containing the completest account of the flora of Malta up to the present time, bringing the total number of species up to 833.

At a meeting of the Society of Arts, last week, Mr. Brudenell Carter read a valuable paper on "Vision-testing for Practical Purposes." Referring to colour blindness, Mr. Carter said that Dr. Joy Jeffries, in the last edition of his work on the subject, tabulates the results of the examination of 175,127 persons, and shows that the percentage of this number who were colour blind amounted to 3·95. Any method of examination which gives a percentage differing from this in any marked degree must, Mr. Carter thinks, be vitiated by some error. Of the methods of examination pursued on the English and Scottish lines of railway, and by the Board of Trade, he said they had one feature in common—they were all wrong, "the direct offspring, in almost every instance, of a degree of ignorance and presumption, the very existence of which would be incredible if the proofs of it were not brought daily under our observation." "Even where the use of Holmgren's method is professed," said Mr. Carter, "the rules laid down by Holmgren for conducting it are, as a rule, utterly ignored, and the results obtained are as utterly misleading. The test should be used in exact conformity with his very detailed and precise instructions, or it should not be used at all."

The first of a series of Friday evening lectures on Astronomy was delivered on Friday, the 24th instant, by Mr. E. J. C. Morton, at the Battersea Public Baths. An audience numbering over 400 assembled, and manifested much interest in the subject with which Mr. Morton dealt. The lectures are being given in connection with the University Extension Scheme.

The following science lectures will be given at the Royal Victoria Hall during February: 4th, "Algeria and Morocco," by Mr. Henry Blackburn; 11th, "Arsenic," by Mr. Ward Coldridge; 18th, "Eyesight and Some of its Defects," by Dr. Collins; 25th, "Sinai and Palestine," by Sir Charles Wilson.

The third series of lectures given by the Sunday Lecture Society will begin on Sunday afternoon, February 2, in St. George's Hall, Langham Place, at 4 p.m., when Dr. B. W. Richardson, F.R.S., will lecture on "The Health of the Mind; and Mental Contagions." Lectures will subsequently be given by Sir Henry E. Roscoe, M.P., F.R.S., Mr. Justin H. McCarthy, M.P., Mr. G. Wotherspoon, Mr. H. L. Brækstad, Mr. Louis Fagan, and Dr. James Edmunds.

Great efforts are being made to secure that the eleventh meeting of the National Electric Light Association, to be held

at Kansas City from February 11 to 14, shall be, as *Science* puts it, "one of the most interesting conventions ever held." Those who propose to go to Kansas from New York may look forward to a pleasant journey. A vestibule train, to be called the Electric Limited, is to run through without change to Kansas City *viâ* Chicago and the Chicago, Burlington, and Quincy Railroad. The committee making the necessary arrangements feels confident that this train will be "the finest ever run out of New York." It will be composed of the latest Pullman vestibule sleeping-cars, lighted by electricity, a dining-car, composite car containing barber shop, bath room, card room, library, writing desk, smoking room, &c., and an observation car with a large open room luxuriously furnished, as well as an observation platform. The train will be supplied throughout with fixed and portable electric lamps.

HERR TRAUTWEILER thinks that a railway should go to the top of the Jungfrau, and in the *Schweizerische Bauzeitung* gives a brief account of his scheme. The railway would go from the valley below to the summit, and would be almost entirely underground. There would be several intermediate stations, from which convenient, well-arranged tunnels would lead to points on the mountain whence the best views are to be had. If stormy weather came on, the passengers could withdraw into the shelter of those tunnels. The railway would be lighted by electricity.

THE following is translated from a notice published by the authorities of the Madrid Observatory:—"D. Ernesto Caballero, Professor of Physics, and director of the electric lighting manufactory in Pontevedra, writes to this Observatory, giving details of a remarkable meteorological phenomenon which appeared at 9.15 p.m. on the 2nd inst. In a sky serene and clear, there appeared suddenly a globe or ball of fire of the apparent size of an orange, which after falling (it is not possible to well indicate how or from whence) upon the conducting wires stretched across the city, entered the manufactory (referred to) by a skylight or window, struck the apparatus for distributing the light, from which (after raising the armature of a magnetic current closer) it struck the dynamo at work. In the presence of the alarmed engineer and workmen present it rebounded twice from the dynamo to the conductor, and from the conductor to the dynamo, then fell and burst with a sharp and clear detonation into a multitude of fragments, without producing any harm or leaving any trace of its mysterious existence. In various parts of the city the lights swiftly oscillated and were extinguished for some seconds, and that the darkness was not general and long continued was owing to the admirable self-possession of the *employés*, who almost instantly established the order of things so suddenly and strangely interrupted by this mysterious meteor, of whose action and presence there only remained traces on the melted (or soldered) edges of the thick copper plates belonging to the armature of the circuit closer. Outside the building, and at the moment of falling upon the conducting wires, it was seen by (among others) the Professor of Natural History, Señor Garcéran, and from various effects observed on the wires during the following day there were undoubted manifestations (in no other way explicable) of its electrical origin."

THE second part of a voluminous bibliography of meteorology prepared by Brigadier-General Greely, Chief Signal Officer of the United States Army, and edited by Oliver L. Fassig, has been issued, and consists of a classed catalogue of printed literature relating to moisture, from the origin of printing to the close of 1881. The whole literature included is divided into 22 subdivisions, a comprehensive classification which will be highly appreciated. A section is devoted to rainfall in general, others to distribution and variation of rainfall, others to heavy rainfall and drought, and so on throughout the whole work. A division on "Showers of Miscellaneous Matter," though not properly a part of the subject, has been deemed of sufficient interest in connection with the general subject of precipitation to be included within this volume. Although supplements to Part I. Temperature, and Part II. Moisture, may appear later, it is to be regretted that it will be impracticable for any other part of this bibliography to be issued from the Signal Office.

IN *Petermann's Mitteilungen* for December last, Dr. R. Spitaler has an instructive paper on the temperature "anomalies" of the surface of the earth in January and July, with charts showing those districts which are too warm (in positive anomaly) or too cold (in negative anomaly), compared with the normal values of their geographical positions. Such charts were first drawn by Dove; but as the materials at the disposal of Dr. Spitaler are much better than those which Prof. Dove possessed, the charts differ in several important particulars. The influence of the warm and cold ocean-currents upon the temperature anomaly is very clearly shown. Europe, for instance, being under the influence of the Gulf Stream and south-west winds, is always in positive anomaly, whereas Central Asia is a district which has in winter 24° C. of negative anomaly, while in summer it has 6° of positive anomaly, or of greater heat than the same latitude in Europe. The July chart shows in the northern hemisphere two decided maxima of positive anomaly, and two minima, while in the southern hemisphere, owing to the less amount of land, the anomaly is much smaller. In July the continents of the northern hemisphere are almost entirely in positive anomaly, while the whole of the Atlantic and Pacific Oceans and Central America are in negative anomaly.

IN the current number of the Journal of the Anthropological Institute there is a valuable paper, by Dr. Arthur Thomson, on the Veddahs of Ceylon. Discussing the affinities of the Veddahs, he says there appears to be little doubt that if they be not of the same stock as the so-called aborigines of Southern India they at least present very strong points of resemblance as regards stature, proportions of limbs, cranial capacity, and form of skull. The similarities of hair and colour between these races have often been remarked, so that, on the whole, if physical features alone be taken into account, Dr. Thomson thinks the affinities of the Veddahs with the hill tribes of the Nilgherries and the natives of the Coromandel coast, and the country near Cape Comorin, are fairly well proved.

MR. H. B. BASHORE sends to *Science* sketches of an interesting Indian pipe. It is made of dark green steatite, carved into an admirable image of a turtle, and represents, no doubt, one of the Delaware totems. The back of the animal is well polished and distinctly marked with lines, and the hole for the stem is well drilled, and of a smooth bore. This relic was found thirty years ago on the site of what is now the village of Fairview, on the Susquehanna, close to an old Indian burying-ground.

THE Punjab Government is obtaining a number of young olive trees from Italy, and proposes to find out by experiment whether the low hills below Murree in the Rawul Pindi district are suitable for olive cultivation.

THE Laccadive Islands have been suffering severely from a plague of rats. According to the Calcutta Correspondent of the *Times*, these invaders have destroyed the cocoanut plantations and reduced the islanders to a state of destitution.

MR. R. M. JOHNSTON lately called the attention of the Royal Society of Tasmania to the extreme variability of the genus *Unio*, inhabiting the northern rivers of Tasmania. The shell seems to be capable of a remarkable number of modifications with regard both to form and colour. This, Mr. Johnston says, is more particularly the case if specimens marking different stages of growth are compared with each other. In specimens

marking seven stages of growth, the variation in form—from youth to the adult stage—embraces characteristics covering "most of the distinctions upon which many of the Australian forms mainly depend for the recognition of distinct specific rank." Such being the variability of local form in the individuals of the various stages of growth, Mr. Johnston thinks there is good reason for the belief that the several forms erected into specific ranks in various parts of Australia may prove to be local varieties, or particular stages of growth of one widely distributed species.

THE destruction of the native opossum is attracting some attention in Tasmania. It is said that about 75 per cent. of the animals killed have had young in the pouch at the time. The opossum has great commercial value, and there seems to be a general opinion that it ought to be efficiently protected.

IN the third report of the Liverpool Marine Biological Station on Puffin Island, Prof. W. A. Herdman gives a concise and interesting account of much good work done during the past year. In the autumn the station was closed, but it will be reopened at the beginning of either April or May, and Prof. Herdman has no doubt that next summer all the different lines of investigation hitherto started will be followed up with a renewed enthusiasm which will more than make up for the loss of the winter observations.

THE *Annuaire de l'Académie Royale de Belgique* for the current year contains the usual information about the Academy and the awards of the various prizes. There is little to interest nonmembers except the series of biographies and portraits of former distinguished members, including Houzeau.

DR. C. HART MERRIAM, chief of division of ornithology and mammalogy, in the U.S. Department of Agriculture, has issued a series of directions for the measurement of small mammals and the preparation of museum skins. The directions are accompanied by an illustration, showing the appearance of a well made skin.

MR. DE ZILVA WICKREMASINGHE, assistant librarian of the Colombo Museum, has compiled a valuable list of the "Pansiyapanas Játaka," the 550 birth stories of Gautama Buddha. In order to make the record complete the compiler consulted many old manuscripts belonging to temple libraries in various parts of Ceylon. The list has been published in the Journal of the Ceylon branch of the Royal Asiatic Society, and is also printed separately.

SOLUTIONS to the questions in Pure Mathematics, Stages I. and II., set at the May examinations of the Science and Art Department from 1881 to 1886, have been published by Messrs. Chapman and Hall in book form. Each of the questions has been fully worked out, and together they make a useful series of examples in elementary mathematics.

MESSRS. DULAU AND CO. have issued a catalogue of works relating to cryptogamic botany.

WE have to acknowledge receipt of £2, sent by Mrs. Morton Sumner towards the payment of the debt on the laboratories of Bedford College, to which we called attention last week.

AN interesting paper is contributed by Prof. Carnelley to the *Philosophical Magazine* for January, in which he attempts to express the periodic law of the chemical elements by means of an algebraic formula. For reasons which are given in detail in the memoir, an expression of the form $A = c(m + \sqrt{v})$ is adopted, where A represents the atomic weight of the element, c a constant, m a member of a series in arithmetical progression, depending upon the horizontal series in the periodic table to which the element belongs, and v the maximum valency or the number of the vertical group of which the element is a member. From a number of approximations, Prof. Carnelley finds that m is best represented by the value 0 in the lithium-beryllium-boron &c., horizontal row, by $2\frac{1}{2}$ in the sodium series, 5 in the potassium series, and $8\frac{1}{2}$, 12, $15\frac{1}{2}$, 19, $22\frac{1}{2}$, &c., in the subsequent rows. Thus m is a member of an arithmetical series of which the common difference is $2\frac{1}{2}$ for the first three members, and $3\frac{1}{2}$ for all the rest. On calculating the values of the constant c from the equation $c = \dfrac{A}{m + \sqrt{v}}$ for 55 of the elements, the numbers are all found to lie between 6·0 and 7·2 with a mean value of 6·6. In by far the majority of cases the value is much closer to the mean 6·6 than is represented by the two extreme limits, thus in 35 cases the values lie between 6·45 and 6·75. If the number 6·6, therefore, is adopted as the value of c, and the atomic weights of the elements are then calculated from the formula $A = 6{\cdot}6(m + \sqrt{v})$, the calculated atomic weights thus obtained approximate much more closely to the experimental atomic weights than do the numbers derived from an application of the atomic heat approximation of Dulong and Petit. The number 6·6 at once strikes one as being remarkably near to the celebrated 6·4 of Dulong and Petit, and Prof. Carnelley draws the conclusion that there must be a connection between the two. This assumption appears to be supported by the following interesting facts. If we assume c to represent the atomic heat, then atomic weight = atomic heat $\times (m + \sqrt{v})$ = atomic weight specific heat $\times (m + \sqrt{v})$; or specific heat $= \dfrac{1}{m + \sqrt{v}}$. On calculating the specific heats of the elements from this equation, they are found to agree remarkably well with the experimental values, except in those cases in which the observed specific heat is known to be abnormal. Again, Bettone has shown that the hardness of the elements is inversely proportional to their specific volumes. If this be so, hardness $= \dfrac{\text{specific gravity}}{6{\cdot}6(m + \sqrt{v})}$; and, on calculating the hardness from this formula, the numbers are again found to agree very closely with the hardness experimentally determined by Bettone. That the periodic law may therefore be approximately expressed by a formula of the type $A = c(m + \sqrt{v})$ appears very probable, and that the number 6·6 is a very close approximation to the value of c appears also to be established. Moreover, the fact that m in the even series represents a whole number, while in the odd series it represents a whole number and a half, corresponds to the well-known difference in chemical properties between the members of these series; and the assumption that the common difference between the first three values of m is only $2\frac{1}{2}$, while between all the rest it is $3\frac{1}{2}$, is borne out by Mendeleeff's statement that the elements of the lithium and sodium rows are more or less exceptional in their nature, and not strictly comparable with the subsequent series.

THE additions to the Zoological Society's Gardens during the past week include two Brown Capuchins (*Cebus fatuellus* ♂♂) from Paraguay, presented by Mr. E. Malateste; a Bonnet Monkey (*Macacus sinicus* ♀) from India, presented by Miss Alice Booth; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. C. Harris; a Green Monkey (*Cercopithecus callitrichus* ♂) from West Africa, presented by Quarter-Master Serjeant Mathison, W.I.R.; a Silver Pheasant (*Euplocamus nycthemerus* ♂) from China, presented by Mr. W. R Rootes; a Malbrouck Monkey (*Cercopithecus cynosurus* ♂) from Rorke's Drift, South Africa, a Bonnet Monkey (*Macacus sinicus* ♀) from India, deposited.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on January 30 = 6h. 40m. 20s.

Name.	Mag	Colour.	R.A. 1890.	Decl. 1890.

(6) R Leonis	Var.	Very red.	9 41 39	+11 56

Remarks.

(1) This nebula is described by Sir John Herschel as "pretty large, cometic, much brighter nucleus south following." The remarks relating to the nebula G.C. 1185 (see p. 257) apply equally in this case, the spectrum not having been recorded. Next in importance to observations of the general character of the spectrum will be observations of differences between the spectrum of the nucleus and that of the "tail." It seems hardly likely that the same spectrum will be given by the dense and sparse portions of the nebula.

(2) This star has a fine spectrum of the Group II. type. Dunér states that bands 2–8 inclusive are visible, and possibly also band 9, all the bands being very wide and dark. The point chiefly requiring attention in a spectrum of this character is the presence or absence of the compound fluting of carbon which extends from about wave-length 468 to 474, it having been suggested that band 9 is simply a contrast band due to the presence of this fluting. The mean wave-length given by Dunér for the edge of band 9 is 476·0, and if the suggestion referred to be of any value, this ought to be coincident with the less refrangible edge of the carbon group. This can only be satisfactorily settled by direct comparisons of the spectrum of the star with that of carbon, obtained in the usual way from a Bunsen or spirit-lamp flame.

(3) Vogel classes this with stars of the solar type. The usual differential observations are required.

(4) A star of Group IV. (Gothard). The usual observations are required (see p. 285).

(5) This is a star of Group VI., Dunér stating that the bands 2–9 are visible. Band 6 is a little weaker than the other carbon flutings. It seems probable that some of the brighter stars of the group will give metallic line absorptions, seeing that they are most probably formed by the cooling of stars like the sun, in which there are only traces of carbon absorption, whilst the line absorption is strongly marked. If the *b* group be present, it will most likely produce an apparent displacement of the carbon fluting to a slightly less refrangible position, its absorption being added to that of carbon. This can readily be determined by comparison with the spirit-lamp flame. Other lines may also appear, but *b* is mentioned as being amongst the more prominent solar lines.

(6) Mr. Espin found bright lines in the spectrum of this variable, when near its maximum in 1889. The star will again be at a maximum on January 30, and observers will therefore have an opportunity of making a more detailed examination of the spectrum. The general spectrum is of the Group II. type. Particular attention should be given to the bright carbon flutings, both at maximum and for some time after, as it seems probable that an increase of carbon radiation will accompany the appearance of the bright lines of hydrogen. The star ranges from about magnitude 6 at maximum to 9·5 at minimum, and the period is 313 days.

A. FOWLER.

THE TOTAL ECLIPSE OF JANUARY 1, 1889.—With a summary of the observations of this eclipse, Prof. Holden has come to the conclusion that coronal forms vary periodically, those of 1867, 1878, and 1889 being of the same form; that the outer corona, terminated in branching forms, suggests the presence of streams of meteorites near the sun, whilst the extension of the corona along and very near the plane of the ecliptic would show that such streams must have long been integral parts of the solar system. The photographs taken just before second and after third contact prove the corona to be, without doubt, a solar appendage. Spectroscopic observations indicate that the true atmosphere of the sun may be comparatively shallow, it being conclusively shown that the length of a coronal line is not always an indication of the depth of the gaseous coronal atmosphere of the sun at that point.—*Observatory*, January 1890.

THE ORBITS OF THE COMPANIONS OF BROOKS' COMET (1889 V., July 6.—The four companions which accompanied this comet were notified as B, C, D, and E, respectively, by Prof. Barnard, of the Lick Observatory (*Astr. Nach.*, 2919), the principal portion being called A. Prof. Bredichin has computed, as far as possible, the orbits of the companions (*Astr. Nach.*, 2949). Taking the elements given by Mr. Chandler for the principal mass A, the following elements have been found for C and E; all are reduced to mean equinox 1889·0:—

Elements of A's Orbit.	Elements of C's Orbit.
T = 1889 October 2·1112	T = 1889 October 1·3369
$\omega = 344°\ 29'\ 20''.6$	$\omega = 344°\ 11'\ 47''.1$
☊ = 17 52 19·0	☊ = 17 15 24·5
ι = 6 5 6·9	ι = 6 5 6·2
ϕ = 28 2 11·6	ϕ = 28 2 13·2
log a = 0·565011	log a = 0·505059
Period = 7·0390 years.	Period 7·0402 years.

Elements of E's Orbit.

T = 1889 October 8·7356

$\omega = 347°\ 30'\ 18''.9$

☊ = 17 52 24·5

ι = 6 5 6·2

ϕ = 28 10 10·5

log a = 0·564834

Period = 7·0348 years.

The orbit of the mass B is situated between the orbits of A and C, and the orbit of D between those of C and E. From the inclination and position of the node it is evident that the division of the comet was effected in the plane of A's orbit, and the elements of C and E indicate almost the same point for the separation of the comet into these masses. It may be, therefore, that the separation was due to the action of Jupiter.

GREENWICH OBSERVATORY.—The Astronomer-Royal has issued the Greenwich Observations for 1887. An additional feature is the ten-year catalogue of 4059 stars, deduced from observations extending from 1877 to 1886, and reduced to the epoch 1880. The work, therefore, appears more bulky than ever.

THE PHYSICAL AND CHEMICAL CHARACTERISTICS OF METEORITES AS THROWING LIGHT UPON THEIR PAST HISTORY.

IN several articles which appeared in NATURE last year I used the term meteorite as a generic one, to include all meteoritic masses, whether they consist of the tiniest specks which give rise to the instantaneous appearance of a shooting-star in the highest reaches of our air, or of the largest masses which have so far been found after their descent to the earth's surface.

I must now confine it to those masses which have reached the earth's surface, whether large or small, and I have first to refer to the various suggestions which have been made as to their origin.

The members of the Academy of Sciences of Paris were the last to acknowledge their extra-terrestrial origin, and that long after the writings and reasonings of Chladni, to which reference has been made.

Laplace ascribed them to lunar volcanoes,[1] by others it was imagined that they came from our own volcanoes; there were those, also, who held that they came from the sun; while, again, others thought they were fragments of a broken planet.

The theory of the volcanic origin of meteorites, whether lunar or terrestrial, does not satisfactorily explain the orbital motions around the sun, for, if this were their real origin, the meteorites would travel round the earth. Neither does it explain the relations which exist between comets and meteorites, for no one supposes that comets are effects of volcanic action. Further, fragments thus ejected from the earth's surface would be consumed in the journey by the same process which is afterwards to render them visible to us as shooting-stars.

With regard to the theory of the solar origin of meteorites, it is difficult to understand how solid bodies can come from the sun after passing through an immense thickness of the intensely heated solar atmosphere. Then, again, particles shot out from the sun would not travel in an orbit, as the meteorites do, but would simply move outwards in a straight line, and then fall back.

That the meteorites are fragments of a broken planet is supported by a considerable number of facts, but the main difficulty

[1] "Les Météorites," Meunier, p. 112.

is to establish the connection between comets and meteorites, as even the supporters of the theory do not claim that the comets are parts of a broken planet. Then, again, it is only an assumption that such a planet ever existed, and it is difficult to understand how a broken planet should so far disobey the law of gravity as to divide itself into small scattered fragments.

The real parentage of those meteorites which fall on our earth is, therefore, probably cometic, for the association of comets, meteorites, and shooting-stars can no longer be denied, and it is an observed fact that comets do break up.

The discovery of Schiaparelli (1866), and his view that the head of a comet was the largest meteorite in a swarm, of course, put these origins of some meteorites, at all events, out of the question.

Reichenbach (1858) did not consider that the head of a comet was a large meteorite, but a swarm of small ones, and the large meteorites he considered to be built up in some way out of the smaller ones brought into our system by comets. If this view be subsequently confirmed, since we now know that, as suggested by Schiaparelli, comets are nebulous shreds, brought into our system by solar or planetary attraction, it follows that in the nebulæ also we may be only dealing with excessively small masses.

If meteorites, in the restricted sense of the term above referred to, do not exist sporadically in external space, they must be manufactured in our system, and two tests should be open to us: (1) no meteorites should reach us from outer space; and (2) they should bear traces of the process by which they have been built up from cometary materials.

If we can establish this, then we imagine a gradual progression in the size of meteoritic masses from regions where they are so small that luminous collisions are all but impossible, to those regions nearest to a cooling sun, like our own, where there has been the richest supply of cometary material, furnished at successive perihelion passages for the longest time.

With regard to (1), we have the facts that it is only very rarely meteorites fall in displays of shooting-stars, and that when the earth has passed near a comet no increase in the average number of meteorites has been noticed.

The most important piece of evidence on this point, however, has been recently furnished by Prof. Newton, who, from a complete discussion of the data extant from all known falls, has come to the conclusion that all the meteorites now in our collections have come from a single ring of bodies circulating round the sun.

We next come to (2). The most important point to consider here, in the first place, is the very special structure of meteorites.

Thumb Markings.

Regarding the origin of the remarkable pittings of the surfaces of aërolites and aërosiderites, an opinion was lately expressed and advocated by Daubrée,[1] that in their flight through the air they undergo erosion and excavation by joint effects of combustion and fusion, assisted mainly by air vortices attacking most violently certain portions of their surface. An important paper on this subject by Prof. Maskelyne was published immediately afterwards in the *Philosophical Magazine* (of August 1876). It is true that pittings identical in appearance with those of meteorites are found on the surfaces of certain large grains of powder blown unconsumed from the mouths of the large modern rifled ordnance (excellent specimens of this kind received from Prof. Abel and Major Noble having been shown by Prof. Maskelyne to M. Daubrée in the summer of 1875); but two important grounds for exception, in regard to this explanation, are pointed out by Prof. Maskelyne, which must not be overlooked. The closest examination of the molten glaze with which, like other parts of these surfaces, the pittings or depressions of meteorites are coated over, shows no indications of vorticose action of the air, although stream-lines of the glaze from front to rear are of frequent and conspicuous occurrence. The process of atmospheric combination, or combustion, is also rare, if not entirely absent, during the period of most intense operation of the heat, as is shown by particles of metallic iron which are occasionally found embedded in the glaze, and even by cases where the highly oxidizable mineral oldhamite (calcium sulphide), occurring in spherules in the Bustee meteorite, is glazed over equally with the augite without offering any signs of combustion or of the production of cavities where they are exposed.

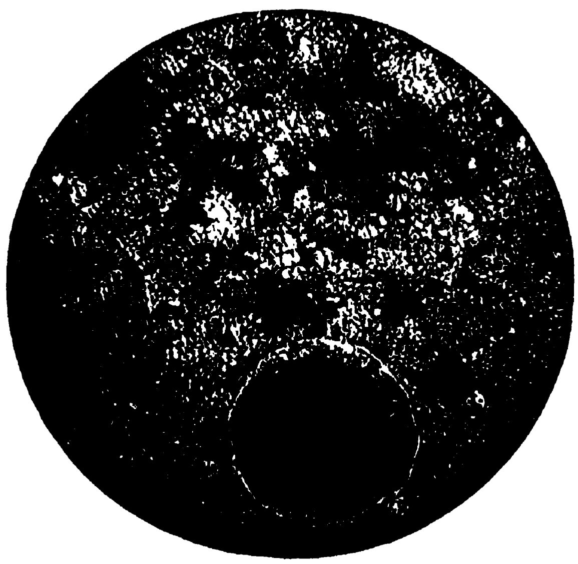
Chondritic Structure.

We have spherules of iron, like small shot of different sizes, in the stones.

These spherules, or chondroi, as they are sometimes called, vary very considerably in size; some reach the size of a cherry, while others are so small that they can only be seen by the aid of a microscope.

Chondroi in Soko-Banya meteorite (magnified 10 diameters)



Chondroi in Mocs meteorite (magnified 10 diameters)

By examining sections of chondritic stony meteorites we find that they consist sometimes almost entirely of spherules. The Parnellee aërolite affords us a very good instance of this, the most varied groups of spherules being seen collected together in one section. These spherules are sometimes encased in small shells of nickeliferous iron, or sometimes in addition with a kind of pyrites, a sulphide of iron termed troilite (FeS), peculiar to meteorites.

Some chondroi have round depressions which point to plasticity during contact, as if the spherules which form the splintered fragments had acquired their form during the act of rubbing. Others, again, have projections of a rounded form, or an almost pointed end.[1]

Our terrestrial rocks contain no structure identical with that chondritic structure so peculiar to meteorites, and the characters of the spherules are found to be quite different from those in either perlite or obsidian.

Tschermak[2] directs attention to the peculiarities observed in several chondritic meteorites. The first is the occurrence of a crust over the surface of the bronzite spherules, possessing fibrous structure. This crust is thin, and is distinguished from the inclosed material by its paler colour; it has the same fibrous

[1] Flight, "History of Meteorites," p. 207.
[2] Quoted from "Report of Observations of Luminous Meteors during the Year 1877–78," p. 107.

structure, doubly refractive power, and, in fact, is optically orientated like the inclosed silicate. It appears to be produced by some agent acting from without, perhaps heat in conjunction with a reducing gas. The agent has not caused friction, but a slight modification of the texture of the surface.

Indications afforded by Crystalline Structure.

The mixed minerals of meteorites have been subjected to microscopic examination by Sorby[1] and Rose,[2] and both have found that the crystals differ in some essential particulars from those of volcanic rocks.

Sorby long since showed that when crystals are formed by deposition from water or from a mass of melted rock, they often catch up portions of this water or melted stone which can be seen as cavities containing fluid or glass. Crystalline minerals formed by purely aqueous or by purely igneous processes can thus be distinguished. One of the most common of the minerals in meteorites is olivine, and when met with in volcanic lavas this mineral usually contains only a few and small glass cavities in comparison with those seen in such minerals as augite. The crystals in meteorites are generally only small, and thus the difficulty of the question is considerably increased. However, by careful examination with high magnifying power, Sorby found well-marked glass-cavities, with perfectly fixed bubbles, the inclosed glass being sometimes of brown colour and having deposited crystals. On the contrary he was never able to detect any trace of fluid-cavities. with moving bubbles, and therefore he holds it very probable, if not absolutely certain, that the crystalline minerals in meteorites were chiefly formed by an igneous process, like that which has produced lava, and analogous volcanic rocks.

Passing from the structure of the individual crystals to that of the aggregate, Sorby points out that in some cases we have a structure in every respect analogous to that of erupted lavas, though even then there are very curious differences in detail.

The results of the observations of the kinds of crystallization noted in meteorites by many eminent authorities go to show that it took place hastily. Thus Brezina, after making a complete study of the Vienna collection, comes to the conclusion that the structural features of meteorites are the result of a hasty crystallization.

Again, it is the opinion of several high authorities that the crystallization did not necessarily take place under conditions of high temperature.

M. Daubrée's opinion is thus expressed :—[3]

"It is extremely remarkable that, in spite of their great tendency to a perfectly distinct crystallization, the silicate combinations which make up the meteorites are there only in the condition of very small crystals, all jumbled together as if they had not passed through fusion. If we may look about us for something analogous, we should say that, instead of calling to mind the long needles of ice which liquid water forms as it freezes, the fine-grained texture of meteorites resembles rather that of hoar frost, and that of snow, which is due, as is known, to the immediate passage of the atmospheric vapour of water into the solid state."

This possibility of the absence of high temperature is thus further insisted upon by Prof. Newton :—[4]

"The meteorites resemble the lavas and slags of the earth. These are formed in the absence of water, and with a limited supply of oxygen, and heat is present in the process. But is heat necessary? Some crystallizations do take place in the cold; some are direct changes from gaseous to solid forms. We cannot in the laboratory reproduce all the conditions of crystallization in the cold of space. We cannot easily determine whether the mere absence of oxygen will not account fully for the slag-like character of the meteoric minerals. Wherever crystallization can take place at all, if there is present silicon and magnesium and iron and nickel, with a limited supply of oxygen, their silicates ought to be expected in abundance, and the iron and nickel in their metallic forms. Except for the heat, the process should be analogous to that of the reduction of iron in the Bessemer cupola, when the limited supply of oxygen combines with the carbon, and leaves the iron free."

Should this view be subsequently confirmed, all early ideas touching the formation of meteorites will require to be modified. Thus, in 1855, Prof. Lawrence Smith stated: "They have all been subject to a more or less prolonged igneous action corresponding to that of terrestrial volcanoes." Haidinger, in 1861, not only declared for high temperature, but for high pressure.

Obviously, these views, which were based more upon the analogues of some of the meteorites with volcanic basic rocks than upon the actual character of the crystallization, suggested the formation of large masses; and the ideas that comets were solid bodies and that meteorites were fragments of comets or planets were both based upon these views,[1] and the higher the temperature required and the slower the crystallization, the larger in imagination did these possible birthplaces of the meteorites become.

If neither much time nor heat be required to produce the crystallization observed, then, with Prof. Newton, we can suppose "a mass containing silicon, magnesium, iron, nickel, a limited supply of oxygen, and small quantities of other elements, all in their primordial or nebulous state (whatever that may be), segregated somewhere in the cold of space. As the materials consolidate and crystallize, the oxygen is appropriated by the silicon and magnesium, and the iron and nickel are deposited in metallic form. Possibly the heat developed may, before it is radiated into space, modify and transform the substance. The final result is a rocky mass (or possibly several adjacent masses) which sooner or later is, no doubt, cooled down throughout to the temperature of space."

We shall see subsequently that there are many known causes in operation which will provide us with just such a mixed mass of vapours as Prof. Newton requires, and it is at once obvious that, not only is the generic separation into iron and stones thus accounted for, but the special form of crystallization observed in stones and the special chondritic structure observed both in irons and stones would all arise from the same cause.

Evidences of Heating and Action of Violent Forces at Different Times.

The peculiarities in the mineralogical structure of the meteorites are probably in part due to the successive heatings and coolings to which they were subjected with each approach of the comet to the sun, and partly, perhaps, to the heat of combination of oxygen and silicon. They were most probably formed in a limited supply of oxygen, so that the elements possessing greatest affinity for that element were the first to form compounds, leaving iron and nickel in the metallic or uncombined state.

Some meteoric stones from examination seem to have been heated to a high temperature right through their mass. Such cases as Orvinio, Chantonnay, Juvenas, and Weston show signs that fragments are cemented together with a material of the same substance as themselves. Again we have indications of chemical changes, the chondroi in some stones being found to be surrounded by spherical and concentric aggregations of minute particles of nickel, due, as is supposed, to the reducing action of hydrogen at a high temperature.

Some meteorites are merely breccias, consisting of fragments, the *débris* of pre-existing meteorites, or of the original mass tremendously shattered, and subsequently cemented together.

In this connection Sorby writes:—

"It would therefore appear that, after the material of the meteorites was melted, a considerable portion was broken up into small fragments, subsequently collected together, and more or less consolidated by mechanical and chemical actions, amongst which must be classed a segregation of iron, either in the metallic state or in combination with other substances. Apparently this breaking up occurred in some cases when the melted matter had become crystalline, but in others the forms of the particles lead me to conclude that it was broken up into detached globules whilst still melted (Mezö-Madaras, Parnellee). This seems to have been the origin of some of the round grains met with in meteorites; for they occasionally still contain a considerable amount of glass, and the crystals which have been formed in it are arranged in groups, radiating from one or more points on the external surface, in such a manner as to indicate that they were developed after the fragments had acquired their present spheroidal shape (Aussun, &c.). In this they differ most characteristically from the general type of concretionary globules found in terrestrial rocks, in which they radiate from the centre; the only case that I know at all analogous being that of certain Oolitic grains in the Kelloways rock at Scarborough, which have undergone a secondary crystallization."[2]

Mr. Sorby remarks: "A most careful study of their microscopical structure leads me to conclude that their con-

[2] "Microscopical Structure of Meteorites," Proc. R.S., June 16, 1864.

stituents were originally at such a high temperature that they were in a state of vapour, like that in which many now occur in the atmosphere of the sun, as proved by the black lines in the solar spectrum." We may, in fact, look upon them as being to planets what the minute drops of water in the clouds are to an ocean. He has shown that possibly, after the condensation of the vapour, they collected into larger masses, which have been subsequently changed by metamorphic action, broken up by mutual impact, and again collected and solidified, the meteoric irons possibly being those portions of the metallic constituents which were separated from the rest by fusion when the metamorphosis was carried to the extreme point.

In this manner the subsequent heating, or any number of subsequent heatings, are explained.

Iron Meteorites not fused in falling.[1]

A question of no slight interest in regard to the changes which meteoric irons undergo during their passage through the atmosphere is whether their surface becomes fused. From his study of the Charlotte meteorite, Dr. Smith is inclined to answer it in the negative. The fact of the delicate reticulated surface having been preserved is a proof that the heat, instead of having been raised to a high temperature, has quickly been conducted away into the mass of metal. Had fusion of the superficial layer taken place, the meteorite would have been coated with molten oxide.

Veins.

Now and again we come across meteorites which have veins, like terrestrial rock-veins, running right through them. Prof. Maskelyne's description of them is as follows:-

"Just as in a mine one may meet with a fissure that, once dividing the 'country,' but subsequently filled by rocky matter, cuts across the course of a mineral vein which itself was originally formed in a similar way; and just as such a cross fissure, thus intersecting with the original metalliferous vein, often gives us evidence of a heave, *i.e.* that one side of the new fissure has slid upwards or downwards along the other, so an exactly similar thing is met with in meteorites, and is admirably seen in the microscopic sections of them."

Faults and throws are both represented in meteorites. In that of Aumières there is a throw of several centimetres indicated, and faults intersect. These faults are accompanied by heat due to the friction of the surfaces, and in the case of gray stony meteorites the faults are black like the crust.[3] (The black veins are physically connected with the crust, and are supposed to have the same origin, the melted material having filled up the fissures.)

On examining such meteorites as Château-Renard, Pultusk, and Alessandria, it is found that some of the spherules even are broken in half and the halves separated from each other by a vein of meteoric iron or troilite, and in some cases by a black fused substance, like the crust of a meteorite.

The Presence of Sulphides.

The presence of sulphides, which must have been formed when both water and free oxygen were absent, shows a distinctly non-terrestrial condition, as, indeed, does also the presence of small particles of iron. On this point Dr. Flight remarks:[4] "If the conditions necessary for the formation of pure calcium sulphide be borne in mind, the evidence imported into this inquiry by the Bustee aërolite seems further to point to the presence of a reducing agent during the formation of its constituent materials."

Sorby's General Conclusions.

We have before referred to Sorby's microscopical examination of meteorites. In 1865 he stated the general conclusions he had arrived at as follows. It will be seen how remarkable the agreement is between him and Reichenbach.

"As shown in my paper in the Proceedings of the Royal Society (xiii. 333), there is good proof of the material of meteorites having been to some extent fused, and in the state of minute detached particles. I had also met with facts which seemed to show that some portions had condensed from a state of vapour; and expected that it would be requisite to adopt a modified nebular hypothesis, but hesitated until I had obtained more satisfactory evidence. The character of the constituent particles of meteorites and their general microscopical structure differ so much from what is seen in terrestrial volcanic rocks, that it appears to me extremely improbable that they were ever portions of the moon, or of a planet, which differed from a large meteorite in having been the seat of a more or less modified volcanic action. A most careful study of their microscopical structure leads me to conclude that their constituents were originally at such a high temperature that they were in a state of vapour, like that in which many now occur in the atmosphere of the sun, as proved by the black lines in the solar spectrum. On cooling, this vapour condensed into a sort of cometary cloud, formed of small crystals and minute drops of melted stony matter, which afterwards became more or less devitrified and crystalline. This cloud was in a state of great commotion, and the particles moving with great velocity were often broken by collision. After collecting together to form larger masses, heat, generated by mutual impact, or that existing in other parts of space through which they moved, gave rise to a variable amount of metamorphism. In some few cases, when the whole mass was fused, all evidence of a previous history has been obliterated; and on solidification a structure has been produced quite similar to that of terrestrial volcanic rocks. Such metamorphosed or fused masses were sometimes more or less completely broken up by violent collision, and the fragments again collected together and solidified. Whilst these changes were taking place, various metallic compounds of iron were so introduced as to indicate that they still existed in free space in the state of vapour, and condensed amongst the previously formed particles of the meteorites. At all events the relative amount of the metallic constituents appears to have increased with the lapse of time, and they often crystallized under conditions differing entirely from those which occurred when mixed metallic and stony materials were metamorphosed, or solidified from a state of igneous fusion in such small masses that the force of gravitation was too weak to separate the constituents, although they differ so much in specific gravity. (Report of British Association, 1864.) Possibly, however, some meteoric irons have been produced in this manner by the occurrence of such a separation. The hydro carbons with which some few meteorites are impregnated may have condensed from a state of vapour at a relatively late period.

"I therefore conclude provisionally that meteorites are records of the existence in planetary space of physical conditions more or less similar to those now confined to the immediate neighbourhood of the sun, at a period indefinitely more remote than that of the occurrence of any of the facts revealed to us by the study of geology—at a period which might in fact be called *pre-terrestrial.*"

Are Meteorites merely Modern Phenomena?

It has often been a subject of remark that in spite of the very considerable number of undoubted meteorites now in various collections, we scarcely have traces of any which suggest like falls in any of the geological periods preceding the present one.

The iron found by Prof. Nordenskiöld at Ovifac, Western Greenland, was at first thought to be meteoric iron of Miocene age, but after an analysis of the basalt or lava rocks of Assuk, Disco Island, a part of the same basaltic range in Greenland, only 100 miles from the spot where Prof. Nordenskiöld's discovery was made, it was held by most authorities to be no other than the metallic nickel-iron which is, though extremely rarely, a native product in some terrestrial rocks. Other explorers besides Prof. Nordenskiöld have brought back specimens of this iron, and Dr. Lawrence Smith has stated, not only that the nickel-iron of Ovifac is without doubt of terrestrial origin, but that the specimens brought back by the other explorers resembles the Ovifac and each other remarkably, while they differ from meteoric iron by the large proportion of combined carbon in their composition.

Again, in NATURE, vol. xxxv. p. 36, we have a description of another meteorite supposed to be a fossil one, found in a block of Tertiary coal. It was said to belong to the group of meteoric irons, and was taken from a block of coal about to be used in a manufactory of Lower Austria. On its examination by various specialists, different origins were assigned to it. Some believed it to be meteoric, others an artificial production, and others again thought it was a meteorite modified by the hand of man. After a careful examination Dr. Gurlt came to the conclusion that there was no ground for believing in the intervention of human agency. The mass was almost a cube, two opposite faces being rounded, and the four others being made smaller by these roundings. A deep incision ran all through the cube. The

[1] Quoted from the "Report on Observations of Luminous Meteors during the year 1874–75," p. 247.
[2] NATURE, vol. xii. p. 505.
[3] Flight, *loc. cit.*, p. 111.
[4] *Loc. cit.*, p. 119.

faces and the incision bore such characteristic traces of meteoric iron as to show that the mass was not the work of man. A layer of oxide formed a thin covering of the iron; it was 67 mm. high, 67 mm. broad, and 47 mm. at its thickest part; it was found to be about as hard as steel, and besides carbon it contained a small percentage of nickel. It resembled the meteoric masses of St. Catherine in Brazil, and Braunau in Bohemia, found in 1847.

The evidence, however, is so strong that what we really obtain now at the earth's surface forms but a very small portion of the meteorites which enter the upper air, that it would not be probable that in former ages of the earth's history, when the atmosphere was denser than it is now, anything whatever would be left by the time the surface was reached.

J. NORMAN LOCKYER.

SCIENTIFIC SERIALS.

American Journal of Science, January.—Measurement of the Peruvian arc, by E. D. Preston. In this paper, which was read before the American Association for the Advancement of Science at Toronto, August 1889, the author reviews the whole question of the relative lengths of the earth's axes, dealing in detail with Bouguer's expedition to Peru in 1735, and arguing that the amplitude of his Peruvian arc may be in error by many seconds. Hence he contends that the geodetic science of to-day demands the remeasurement of this arc.—Neutralization of induction, by John Trowbridge and Samuel Sheldon. A system of neutralization for inductive disturbances is here described, which might be adopted where it is impossible to employ entire metallic circuits in which the earth plays no part.—Divergent evolution and the Darwinian theory, by Rev. John T. Gulick. The author discusses Darwin's apparently contradictory views on the causes of natural selection on the one hand, and on the other on the causes of diversity of natural selection. He concludes that, though Darwin has not recognized segregation as a necessary condition of divergence of species, he has indicated one process (geographical or local separation under different environments) by which segregation is produced in nature, adding, however, that this is not the only cause of segregation and consequent divergence.—The Devonian system of North and South Devonshire, by H. S. Williams. During a recent visit to England the author studied this system both on the spot and in the geological collections in London and elsewhere. He dwells especially, (1) on the close resemblance of the English Devonian species to those of the New York Devonian, though mostly passing under different names, and (2) on the character of the North and South Devonian rocks, which in appearance, composition, and order are as different as two distinct systems well can be.—The zinciferous clays of South-West Missouri, and a theory as to the growth of the calamine of that section, by W. H. Seamon. Full analyses are given of the so-called "tallow" and "joint" clays occurring associated and sometimes intermixed in every calamine digging in South-West Missouri. These analyses show a large percentage, often from 50 to 56, of zinc oxide, and it is inferred that at one time all the massive calamine probably existed in "tallow clays" precipitated from solutions.—On the spectrum of ζ Ursæ Majoris, by Edward C. Pickering.—Origin of normal faults, by T. Mellard Reade. Some critical remarks are offered on Prof. Le Conte's recent explanation of the origin of normal faults, which is not new, and presents many insuperable difficulties.—Papers were submitted by J. Dawson Hawkins, on a specimen of minium from Leadville; by William P. Blake, on some minerals from Arizona; by F. A. Genth, on a new occurrence of corundum in Patrick County, Virginia; by Alfred C. Lane, on the estimation of the optical angle of observations in parallel light; by L. G. Eakins, on a new stone meteorite from Texas; by Edward S. Dana, on the barium sulphate from Perkin's Mill, Templeton, Province of Quebec; and by O. C. Marsh, on some new Dinosaurian reptiles recently discovered in Wyoming, Colorado, and Dakota.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 9.—"A Milk Dentition in *Orycteropus*." By Oldfield Thomas, Natural History Museum. Communicated by Dr. A. Günther, F.R.S.

Of the few Mammalia in which no trace of a milk dentition has been found, *Orycteropus*, the Aard-Vark, has always occupied a prominent place, owing partly to the peculiar structure of its prominent teeth, and partly to its very doubtful systematic position.

An opportunity has now fallen in my way of proving that it has after all two sets of teeth, those of the first, or milk set, being rudimentary, and probably quite functionless, but nevertheless so far developed as to be all completely calcified, and to be for the most part readily distinguishable by form and position from those of the second or permanent set.

Among the collections in the Natural History Museum there are two very young females of *Orycteropus afer* in spirit, presented by Sir Richard Owen, and it is in these that the milk teeth now to be described occur. The larger of the two measures 18 inches in total length, and the smaller 14 inches.

Each of these specimens has a complete, although rudimentary, set of milk teeth, extending the whole length of the maxillary bones above, and along a rather shorter portion of the mandible below. None, however, are observable in the premaxillæ, or in the corresponding anterior part of the mandibles. The teeth are all quite minute, and it is doubtful whether they would ever have cut the gum.

In the upper jaw there appear to be normally no less than seven milk teeth. Of these the most posterior is by far the largest, has a rudimentary crown, and two distinct roots, anterior and posterior. The others are simple and styliform.

In the lower jaw there are four milk teeth only, of which, again, the most posterior is more or less molariform.

As to the structure of the milk teeth, a horizontal section of the last upper one, ground down in the dry state, presents numerous large openings which are obviously the sockets into which pulp-papillæ have extended, so that the milk teeth show a commencement of the remarkable histological structure characteristic of the permanent teeth.

But important as a knowledge of the presence of a milk dentition in *Orycteropus* is, it does not at present render any easier the difficult questions as to the phylogeny and systematic position of that animal. Although called an Edendate, it has always been recognized as possessing many characters exceedingly different from those of the typical American members of the order.[1] It has in fact been placed with them rather on account of the inconvenience of forming a special order for its reception than because of its real relationship to them. Now, as they are either altogether toothless or else homodont and monophyodont (apart from the remarkable exception of *Tatusia*), it seems more than ever incorrect to unite with them the solitary member of the *Tubulidentata*, toothed, heterodont, and diphyodont, and differing from them in addition by its placentation, the anatomy of its reproductive organs, the minute structure of its teeth, and the general characters of its skeleton.

But if *Orycteropus* is not genetically a near relation of the Edendates, we are wholly in the dark as to what other Mammals it is allied to, and I think it would be premature to hazard a guess on the subject. Whether even it has any special connection with *Manis* is a point about which there is the greatest doubt, and, unfortunately, we are as yet absolutely without any palæontological knowledge of the extinct allies of either. *Macrotherium* even, usually supposed from the structure of its phalangeal bones to be related to *Manis*, has lately proved (see Osborn, *American Naturalist*, vol. xxii. p. 728, 1882) to have the teeth and vertebræ of a Perissodactyle Ungulate, and one could not dare to suggest that the ancestors of *Manis* or *Orycteropus* were to be sought in that direction. Lastly, as the numerous fossil American Edentates do not show the slightest tendency to an approximation towards the Old World forms, we are furnished with an additional reason for insisting on the radical distinctness of the latter, whose phylogeny must therefore remain for the present one of the many unsolved zoological problems.

Physical Society, January 17.—Prof. W. G. Adams, Vice-President, in the chair.—Owing to the unavoidable absence of Mr. F. B. Hawes, his paper on a carbon deposit in a Blake telephone transmitter was postponed.—Dr. S. P. Thompson made a communication on electric splashes, and illustrated his subject by beautiful experiments on the production of Lichtenberg's figures. The author has recently investigated these phenomena as modified by varying the conditions under which

[1] On this subject see especially Flower, "On the Mutual Affinities of the Animals composing the Order Edentata," Zool. Soc. Proc., 1882, p. 358 *et seqq.*

the figures are obtained, and has arrived at the following conclusions: (1) the nature of the dielectric plate does not change the character of the figures produced, and (2) the nature of the powders used seems to have no material effect on their shape. In the course of his experiments he has found a mixture of sublimed sulphur and lycopodium to give better figures than the red lead and sulphur usually employed, and also that a large and highly polished knob is advantageous, particularly when the Leyden jar is charged negatively. Sometimes when obtaining negative figures, nebulous patches occur, and these were attributed to the so-called electric winds sent off from roughnesses on the knob when not sufficiently well polished. If instead of bringing the knob in contact with the plate, it is only brought near to it, then a peculiar figure closely resembling a "splash" results. A positive splash consists of short lines radiating from the point of approach, whilst a negative splash is made up of more or less rounded spots which become elongated in a radial direction as their distance from the centre of the splash increases. Negative splashes are, however, much more difficult to produce than positive ones. When viewed in the dark, the discharge producing the splash is seen to consist of a bundle of small sparks which branch outwards on approaching the plate. In conclusion the author remarked that roughnesses on a conductor produced more electric winds when the conductor is charged negatively than when positively charged, and invited the opinions of members as to the causes of the differences observed between positive and negative electricity. Prof. Rücker said he had recently obtained figures produced by discharges on photographic plates. Generally he observed that negative discharges produce roundish patches, whilst positive ones give more filamentary figures. On passing a spark across a glass plate covered with lampblack, its trace was found to have a black core at one end, whilst the other was quite clear. He also made remarks on the distinctive character of the positive and negative discharges in partial *vacuo*, and considered investigations as to the causes of such differences to be of great importance. Prof. Adams thought any attempt to discover the causes of such differences as those noted in the paper was to be commended, for the well-known fact that it is more difficult to insulate a negative charge than a positive one has long needed an explanation.—A paper on galvanometers, by Prof. W. E. Ayrton, F.R.S., T. Mather, and W. E. Sumpner, was read by Prof. Ayrton. In fitting up the Physical Laboratories of the Central Institution of the City and Guilds of London Institute, the authors have had occasion to obtain galvanometers of various types and patterns, some of which have been made to special designs, and specimens of instruments embodying recent improvements were exhibited at the meeting. The question as to whether fairly sensitive galvanometers should be astatic or non-astatic was answered in favour of the former system, from the fact of its being less affected by external magnetic disturbances, and the greater ease with which great sensibility may be obtained. The usual method of placing the mirror inside the coil was shown to be undesirable, and in the newer forms of instruments Mudford's improvement of placing the mirror outside the coils has been adopted; the space near the axis of the coil being nearly filled with wire. It was also shown that if wire be wound in a certain approximately spheroidal space near the magnets, then these convolutions will tend to oppose the more distant portions of the coil; however, by winding the two parts in opposite directions they conspire to deflect the magnet. Details as to methods of supporting the coils were then discussed, and the importance of fitting them in boxes mounted on hinges or otherwise, so as to be readily removable, was pointed out. A galvanometer devised for teaching purposes, and provided with variable damping arrangements was described, in which the damping is effected by enclosing the mirror in a glass cell whose sides can be caused to approach or recede by turning a milled head outside the instrument. This arrangement enables the damping to be varied between wide limits, and its effect on the swing produced by a given discharge can be determined. The instrument is also serviceable both as an ordinary damped galvanometer, or as a fairly ballistic one. In measuring quantities of electricity by the first swing of a galvanometer needle, a correction has usually to be introduced for damping; this correcting factor is simple enough when the damping is small, but becomes more complicated as the damping increases, and to facilitate the calculations a table of values of the factor for various values of λ (the logarithmic decrement) has been calculated. From this it appears that, for values of λ less than 0·5, the value of the factor is very nearly $(1 + \frac{1}{2}\lambda)$, the correction usually employed. Improvements in methods of insulating the coils and terminals of galvanometers required for insulation tests were next described, the principle of which may be gathered from Figs. 107 and 108 in Prof. Ayrton's "Practical Electricity." A special form of instrument for high insulation work was exhibited, in which the copper resistance of the coils is nearly 400,000 ohms, and the shortest path along which surface leakage can take place from the coils to the base of the instrument is between 30 and 40 inches of ebonite artificially dried by sulphuric acid. This is attained by supporting the coils from two corrugated ebonite rods which depend from a brass ring carried on the top of three corrugated pillars fixed to the base plate. The instrument was constructed to drawing and specification by Messrs. Nalder Brothers, but the method of supporting the coils was suggested by Messrs. Eidsforth and Mudford. With reference to the proportionality of deflection to current in reflecting galvanometers, it was pointed out that ordinary instruments may differ as much as 2 per cent. within the limits of the scale, hence showing the necessity for calibration when any approach to accuracy is desired. Galvanometers of the D'Arsonval type sometimes differ from proportionality quite as much as the one above referred to, but by fitting such instruments with curved pole pieces, and allowing the coil to hang freely from the top suspension, a proportionality true to less than 0·15 per cent. has been attained over a scale about 30 inches long. Coming to the question of sensitiveness, the importance of keeping the wire as close as possible to the magnets was brought prominently forward, as well as the necessity of reducing the "figures of merit" of various instruments to the same standard, in comparing their sensibilities. The standard adopted as most convenient and closely approximating to practical usage is arrived at by supposing the distance of the mirror from the scale to be equal to 2000 scale divisions, and the sensibilities for current and quantity are given as *scale divisions per micro-ampere*, and *scale divisions per micro-coulomb* respectively. The period of oscillation is also taken into account. A table showing the resistances, sensibilities, coefficients of self-induction and volumes of the coils of various instruments, together with the relations existing between them, accompanies the paper, and from this it appears that in the best astatic double coil instruments, of from 10,000 to 30,000 ohms resistance, the number of scale divisions per micro-ampere may reach 400 times the resistance to the $\frac{2}{5}$th power ($400\ R^{\frac{2}{5}}$) when the period is 10 seconds. In obtaining data of various instruments the authors have consulted, amongst others, Prof. Threlfall's paper on the measurement of high specific resistances, in the *Phil. Mag.* for December 1889, and noticed two serious errors. The first of these makes an instrument constructed according to Messrs. Gray's pattern nine times less sensitive than it actually was, whilst the sensibility of a form recommended in the paper is given seventeen times too great. On account of the lateness of the hour, the discussion was adjourned till February 6, before which time it is hoped that a fairly full abstract will appear in the technical papers.

Geological Society, January 8.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—On some British Jurassic fish-remains referable to the genera *Eurycormus* and *Hypsocormus*, by A. Smith Woodward. Hitherto our knowledge of the Upper Jurassic fish fauna has been mainly derived from specimens found in fine lithographic stones, where the various elements are in a state of extreme compression. Within the last few years remains of similar fish have been discovered in the Oxford and Kimeridge Clays of England, and these are of value for precise determination of certain skeletal features in the genera to which they belong. The author described *Eurycormus grandis* from the Kimeridge Clay of Ely, a large species which makes known for the first time the form and proportions of several of the head-bones in this genus. A technical description of all the bones the characters of which are distinguishable was given, and the author concluded that there is considerable similarity between the head of *Eurycormus* and the recent Ganoid *Amia*, even to minute points of detail. He further described *Hypsocormus tenuirostris* and *H. Leedsii* from the Oxford Clay of the neighbourhood of Peterborough, the osteology of this genus not having as yet been elucidated. Portions of the jaws have been discovered, affording valuable information as to the form and dentition of the principal elements. These jaws are not precisely paralleled by any other Jurassic genus, though they possess a resemblance to *Pachycormus*, as also to the Upper Cretaceous genus, *Protosphyræna*. The President remarked that *Amia* is a

freshwater genus, and inquired whether the fossil fish was freshwater or marine. Mr. E. T. Newton remarked upon the great interest and importance of the paper. The author, in reply to the President's question, said that the old Ganoids were marine, and it was only in more recent times that they had become restricted to fresh water.—On the Pebidian volcanic series of St. David's, by Prof. C. Lloyd Morgan. After a brief sketch of the principal theories that have been propounded, the author concluded that our knowledge of this series has not yet reached "a satisfactory position of stable equilibrium." His own communication was divided into three sections. *The Relation of Pebidian to Cambrian:* There are four localities where the junction is described—Caerbwdy Valley, St. Non's Bay, Ogof Golchfa, and Ramsey Sound. The stratigraphy of the second of these was given with much detail, and illustrated. The author concluded that here, together with clear signs of local or contemporaneous erosion, the general parallelism of the strike of Pebidian and Cambrian is most marked. There is no evidence of any bending round of the conglomerate against the strike of the Pebidians. The stratigraphical evidence in each of the localities having been considered, together with the evidence offered by the materials of the Cambrian conglomerate and local interstratification with the volcanic beds (the interdigitation at Carnarwig being well marked), he concluded that there was no great break between the conglomerate and the underlying Pebidians. The uppermost Pebidian already foreshadowed the sedimentary conditions of the Harlech strata, and the change emphasized by the conglomerate was one that followed volcanic conditions after no great lapse of time. Hence the relation of the Pebidian to the Cambrian is that of a volcanic series, for the most part submarine, to succeeding sedimentary strata—these strata being introduced by a conglomerate formed in the main of foreign pebbles borne onward by a current which swept the surface of, and eroded channels in the volcanic tuffs and other deposits. He was disposed to retain the name Pebidian as a volcanic series in the base of the Cambrian system. *The Pebidian Succession:* With the exception of some cinder-beds, which appear to be subaërial, the whole series was accumulated under water. There is no justification for making separate subdivisions; the series consists of alternating beds of tuff of varying colour and basicity, the prevailing tints being dark green, red-grey, and light sea-green. In the upper beds there is an increasing amount of sedimentary material, and more rounded pebbles are found. Basic lava-flows occur, for the most part, in the upper beds. Detailed work, laid down on the 6-inch Ordnance map, appears to establish a series of three folds—a northern anticline, a central syncline, and a southern anticline—folded over to form an isocline, with reversed dips to the south-east. The axis of folding is roughly parallel to the axis of St. David's promontory. The total thickness is from 1200 to 1500 feet. The author devoted a considerable number of pages to further details concerning this series of deposits. He failed to find the alleged Cambrian overlap. "The probabilities are that it is by step-faults brtween Rhoson and Porth Sele, and not by overlap, that the displacement of the conglomerate has there been effected." Also at Ogof Gôch it does not rest upon the quartz-felsite breccia and sheets (group C, of Dr. Hicks), but is faulted against them. A section was devoted to the felsitic dykes, and it was suggested that they may be volcanic dykes of Cambrian age. *The Relation of the Pebidian to the Dimetian:* The author has not been able to satisfy himself of the existence of the Arvonian as a separate and distinct system. He notes the junction of Pebidian and Dimetian in Porthlisky Bay and the Allen Valley at Porth Clais, at neither of which places are there satisfactory evidences of intrusion. At Ogof Llesugn the intrusive character of the Dimetian was strongly impressed upon him. He criticized the mapping of Dr. Hicks, and pointed out the difficulties which present themselves in the way of mapping the Dimetian ridge as pre-Cambrian. He pointed out that not a single pebble of Dimetian rock, such as those now lying on the beach in Porthlisky Bay, is to be found in the conglomerate. He concluded that the Dimetian is intrusive in the southern limb of the isocline, and that there are no Archæan rocks *in situ*. After the reading of this paper there was a discussion, in which the President, Dr. Hicks, Prof. Blake, Prof. Hughes, and Mr. Williams took part.

SYDNEY.

Royal Society of New South Wales, November 6, 1889.—Monthly meeting.—Prof. Liversidge, F.R.S., President, in the chair.—The Chairman announced the death of the Rev. J. E. Tenison-Woods, who had been an honorary member of the Society since 1875.—The following papers were read:—Aids to the sanitation of unsewered districts, poudrette factories, by Dr. J. Ashburton Thompson.—Notes on Goulburn lime, by E. C. Manfred.—Notes on some minerals, &c., by John C. H. Mingaye.

December 4.—Monthly Meeting.—Prof. Liversidge, F.R.S., President, in the chair.—The following papers were read:—Well and river waters of New South Wales, by W. A. Dixon.—The Australian aborigines, by Rev. John Mathew.

PARIS.

Academy of Sciences, January 20.—M. Hermite in the chair.—On the various states of the carbon graphites, and on the chemical derivatives corresponding to them, by MM. Berthelot and P. Petit. The graphites, when oxidized by the wet process at a low temperature, form ternary compounds, one of whose terms has been discovered by Brodie. But M. Berthelot has since shown that there exist several chemically distinct graphites, each forming a particular graphitic oxide, which yields a corresponding hydrographitic and pyrographitic oxide, and which may be recovered with all their primitive properties. These various graphites and the series of corresponding compounds have been studied, first by their composition and behaviour, and in a second memoir by the measurement of the heats of combustion and formation.—Remarks on the formation of the nitrates in plants, by M. Berthelot. The author points out that the facts established by Haeckel and Lundström, taken in connection with his own observations, tend to show an affinity between the microbes present in the soil and those developed in the plant. This applies to the microbes which fix the nitrogen of vegetable humus and the leguminous plants, as well as to those which similarly form the nitrates in amaranthus, sterculia, the coffee shrub and vegetable humus.—Note on a fundamental point of the theory of polyhedrons, by M. de Jonquières. The paper deals with Euler's famous formula $S + H = A + 2$, and shows that it is applicable, and intended by Euler to be applicable, to all polyhedrons without exception, and not restricted to any particular class, as supposed by Legendre, Cauchy, and others.—Ephemerides for the search of the periodical comet of d'Arrest on its return in 1890, by M. Gustave Leveau. Having previously obtained the elements for the years 1870, 1877, and 1883, by allowing for the disturbing influence of Jupiter, Saturn, and Mars, M. Leveau here supplies those for 1890 (February 25, mean Paris time) by studying the disturbing effects produced by Jupiter in the interval between 1883 and 1890.—Observations of Swift's comet made at the Observatory of Nice with the 0·38 m. equatorial, by M. D. Eginitis.—On the solar statistics for the year 1889, by M. Rud. Wolf. From the solar observations made at Zurich and the magnetic observations recorded at Milan, the author has constructed a table of monthly means showing that both the relative numbers and the magnetic variations have continued to diminish during 1890. But he thinks that the retrograde movement will soon cease, and that we probably entered the minimum period towards the end of last year.—On the theory of the figure of the planets, by M. M. Hamy. An attempt is here made to realize theoretically the conditions of a system answering to M. Poincaré's remarkable theorem published in the *Comptes rendus* for June 1888.—On the integration of an equation with partial derivatives, by M. Zaremba. The paper deals with an equation of the form

$$\frac{d^2x}{dxdy} + \phi_1(x+y)\left(\frac{dz}{dx} + \frac{dz}{dy}\right) + \phi_2(x+y)z = 0,$$

where ϕ_1 and ϕ_2 are two functions whatsoever of $x + y$, and shows that the determination of the general integration may be reduced to the integration of an ordinary linear differential equation of the second order, and to quadratures.—On the variation of the resistance of bismuth in the magnetic field, by M. A. Leduc. The author here continues his studies of the electric resistance of bismuth as affected by varying temperature.—Calculation of the compressibility of nitrogen up to 3000 atmospheres, by M. Ch. Antoine. The results of fresh calculations are here summed up in a table resuming all the data relative to the pressure of nitrogen up to a pressure of 3000 atmospheres.—On the combinations of the metals of the alkalies with ammonia, by M. H. W. Bakhuis Roozeboom. An explanation is offered of the curious phenomena mentioned by M. Joannis in his recent

communication (*Comptes rendus*, cix. p. 900) on the combinations of potassium and sodium with ammonia.—On the absorption of the ultra-violet rays by some organic substances belonging to the fatty series, by MM. J. L. Soret and Alb. A. Rilliet. These studies, which to a large extent confirm the conclusions of Messrs. Hartley and Huntington (Philosophical Transactions of the Royal Society, 1879), show in a general way that the measurement of the absorption of the ultra-violet rays constitutes a delicate means of estimating the purity of organic substances.—On the refracting powers of double salts in solution, by M. E. Doumer. These researches have been carried on by the same method which enabled the author to determine the refracting powers of simple salts. The results, which are here tabulated, show that the molecular refracting power of a double salt is equal to the sum of the molecular refracting powers of the constituent simple salts; and in general, the molecular refracting power of any salt, simple or double, is proportional to the number of valences of the metallic part of the salt.—Papers were read by M. Ph. A. Guye, on the molecular constitution of bodies at the critical point; by M. Raoul Varet, on the reactions between the salts of copper and the metallic cyanides; by MM. C. Chabrié and L. Lapicque, on the physiological action of selenious acid; and by M. L. de Launay, on the geology of the island of Lesbos. M. de Launay considers the volcanic eruptions of this island as comparatively recent, possibly not older than the Pliocene epoch, and doubtless contemporary with the disturbances resulting in the creation of the Ægean Sea in a region previously forming a vast marshy plain with shallow lakes.

TAVERNIER'S TRAVELS IN INDIA.

Travels in India of Jean Baptiste Tavernier, Baron of Aubonne. Translated from the original French Edition of 1676, &c., by V. Ball, LL.D., F.R.S., F.G.S., &c. In Two Volumes. (London: Macmillan and Co., 1889.)

JEAN BAPTISTE TAVERNIER was a Sindbad of the seventeenth century. To an insatiable love of travel, which prompted him even in his boyhood to rove through the greater part of Europe, and in his mature life to accomplish no less than six voyages to Persia, India, and the still more remote East, he united the faculties of a shrewd and successful trader. By his traffic in jewels and other costly commodities of small bulk, he turned his wanderings to profitable account, and amassed a fortune which enabled him to purchase the Barony of Aubonne, and to enjoy the dignified retirement of a wealthy old age. But, like a true traveller, he remained active-minded and active-bodied to the last. At the age of 79, attracted by the offer of the Elector of Brandenburg to conduct an embassy to India, he set forth on a circuitous journey through Europe, and, disposing of his estate and *château* of Aubonne, he embarked on renewed mercantile ventures. The few remaining years of his life were passed, for the most part, in journeying to and fro in Europe, and he died while so occupied. The place of his death has long been doubtful, and it has only recently been discovered, on the authority of a letter from the Swedish Resident at Moscow, that the indefatigable traveller drew his last breath at Smolensk, in February 1689, when on his journey to the ancient Russian capital.

Despite some inaccuracies and inconsistencies, due mainly to the incompetent editing of the original work, Tavernier's account of his travels has long been appealed to by Indian historians as a recognized authority—the testimony of an eye-witness to the condition of India under the later great Mogul emperors. At the time of his visits, the Mogul Empire was in the zenith of its power and splendour. On the occasion of his first journey to India, he found Shah Jehan, "the most magnificent prince that ever appeared in India," peaceably seated on the Imperial *masnad*; and throughout his dominions, though these were less extensive than in the time of his successor Aurungzebe, a degree of good administration and general prosperity surpassing that attained under any previous or subsequent emperor. He quitted India for the last time only about two months after the death of Shah Jehan, then deposed and imprisoned, when Aurungzebe was setting out on that career of conquest and oppression that in the following century brought about the wreck of the Mogul Empire, and exposed its rich cities and provinces to be wasted and despoiled by Maráthá hordes and Afghan invaders.

At a Court gathered around the famous peacock throne, where emperor and nobles vied with each other in the acquisition of costly jewels, an expert such as Tavernier was received as a welcome visitor; and in pursuit of his calling he travelled without hindrance through the length and breadth of India, visiting the European settlements of Surat, Goa, Madras, and Kásimbazár, the independent Court of Golconda (Hyderabad), and certain of the diamond-mines that were then actively worked both in Southern and Northern India. His work is a medley of historical memoranda, incidents of travel, itineraries, and details of his commercial dealings, put together without much system, but nevertheless highly instructive, and apparently far more trustworthy than was conceded to him by most of his contemporaries; altogether furnishing a fund of information respecting the state of India in the middle of the seventeenth century.

The latest English translation of Tavernier's travels appeared more than two centuries ago, and as Mr. Ball remarks, owing to the translator's misconception of the author's meaning, through want of local knowledge, and to serious abridgment, it gives a very inadequate idea of the true merits of the original work. Mr. Ball's own long experience of India, and his familiarity with its geography and the varied phases of native life, would alone have enabled him to correct most of the errors of his predecessors; and the deficiencies as a philological and historical critic which he modestly urges as having determined him, for a time, to abstain from attempting a new translation, have been made good by the invaluable assistance afforded by the late Sir Henry Yule, under whose advice he eventually undertook the work. The result is the two handsome volumes now before us, in which for the first time the old traveller's experiences are presented to English readers, elucidated by the results of modern research, and in a form which very greatly enhances their value for all purposes of future reference. Some few inconsistencies remain, and are duly pointed out in the footnotes, but they are such as relate to matters of detail, occasional confusion of dates or persons, and the like; and they do not appreciably detract from the general trustworthiness of the narration.

With the political and historical data of Tavernier's work it is hardly our province to deal in this place. Most of his facts relating to the Court of Delhi were probably furnished to him by his cotemporary and sometime fellow-traveller Bernier, and all that is important in them has been long rendered familiar to English readers in the lucid pages of Elphinstone. Neither need we dwell on his descriptions of native customs or the manner of life of those European exiles of various nationalities who were then, as pioneers, exploiting the riches of the East, with no small display of mutual jealousy and animosity, and indulgence in practices sometimes hardly less barbarous than those of the indigenous population amid which they dwelt. The social condition of the Indian people in Tavernier's day was essentially the same as when, more than a century and a half later, the British Empire having been raised and consolidated on the ruins left by Maráthás and Patháns, a new era of peace and civilization was inaugurated by Lord Bentinck, and the suppression of thuggi, dacoity, sati, and other barbarous rites of the Hindu religion, preceded the establishment of schools and Universities, and the opening up of the wilds of India by systems of roads and railways. The social regeneration of India, such as it is, has been almost exclusively the work of the last seventy years, and even now it has hardly penetrated far below the surface.

It was the information given by the traveller on the diamond-mines worked in his day, that first drew Mr. Ball's attention to the subject of Tavernier's travels. The mines visited and described by him have long been abandoned, and even their very sites forgotten. With free labour, and at its present enhanced rates, diamond-working is no longer so remunerative as under the despotic governments of the seventeenth century, and it is within the recollection of the present writer that the working of one of the most productive mines of the former Golconda State was let on behalf of the British Government at the modest rental of 100 rupees. Tavernier gives it to be understood, indeed, that only four mines were worked, all of which he visited; but Mr. Ball tells us there is ample reason for believing that they were far more numerous than he had any conception of; and in an appendix he gives a full list of all the Indian localities at which diamonds have been obtained as far as is known, together with the geographical co-ordinates of all such as he has succeeded in identifying. Owing to the vagaries of phonetic spelling, and the ignorance of Indian geography on the part of many who have dealt with this subject, this identification has been far from easy. As amusing examples of the way in which localities have been confused by some previous writers, Mr. Ball tells us that "one author gives Pegu as a diamond-mine in Southern India; in the Mount Catti of another we have a reference to the Ghâts of Southern India"; and he adds: "For some time I was unable to identify a certain Mr. Cullinger, who was quoted by one writer, in connection with diamonds. Will it be believed that this *gentleman* ultimately proved on investigation to be the *fort* of Kálinjar?"—a well-known historical fortress in Bundelkhand.

Indian diamonds are found exclusively in rocks of the Vindhyan formation or in the gravels of rivers that drain these rocks. The formation consists of sandstones, limestones, and other sedimentary rocks, certainly not more recent than the Lower Palæozoic age, but being unfossiliferous, their precise age cannot be determined. In Southern India the diamonds occur only in the Bánaganpili sandstone, at the base of the lower subdivision of the Vindhyan series, or in gravels derived from that bed. This is described by the authors of the "Manual of the Geology of India" as usually from 10 to 20 feet thick, consisting of gravelly, coarse sandstone, often earthy, and containing numerous beds of small pebbles. The diamonds are found in some of the more clayey and pebbly layers, and in the opinion of Dr. W. King, the present Director of the Indian Geological Survey, they are innate in the rock. This view does not, however, appear to commend itself to the authors of the manual. In Northern India, at Panna, in Bundelkhand, the diamond bed is in the upper division of the Vindhyan series; but it is considered not improbable that here also the original *nidus* of the diamonds was, as in Southern India, a bed of the lower subdivision, pebbles of which occur in the diamond bed, and are extracted and broken up in the search for the gem.

As is well known, Tavernier examined, and in his book described and figured, the famous Great Mogul diamond, then in the possession of the Emperor Aurungzebe; and he has been often cited as a principal witness by those who have discussed the question of the history of the Koh-i-noor. To this subject Mr. Ball devotes a long note in the appendix, arriving at conclusions which differ from those of Prof. N. S. Maskelyne, and indeed of most previous writers, with the exception of James Forbes, Major-General Sleeman, and Mr. Tennant. The argument is somewhat complex, and hardly admits of abstraction, and we must therefore refer those who are interested in the subject to the text of Mr. Ball's note. It will suffice here to indicate the main issues. They are concerned with the identification *inter se* of the three diamonds known respectively as the Mogul diamond, Baber's diamond, and the Koh-i-noor. The first of these, described and figured by Tavernier, is the largest diamond on record, and is stated to have weighed originally, before cutting, 900 *ratis* (an Indian weight still in use, but the value of which has varied greatly at different times and under different circumstances). When Tavernier saw it, it had been reduced by unskilful cutting to about two-fifths of its former size, and weighed only 379½ *ratis*, which Mr. Ball computes to be equivalent to 268 English carats. Baber's diamond, of which Tavernier makes no mention, but which is equally historic, Mr. Ball thinks was probably retained by the imprisoned Shah Jehan, and acquired by Aurungzebe only after Shah Jehan's death. The weight of this stone is computed by Mr. Ball, from the statements of Baber and Ferishta, to have been 186 English carats. The weight of the Koh-i-noor when first brought to England was exactly the same as that computed for Baber's diamond, or, accurately, 186·06 carats. Now Prof. Maskelyne, General Cunningham, and several other writers regard these three stones as identical, and the former suggests that Tavernier's estimate of the weight of the Great Mogul diamond in carats (probably Florentine) was erroneous, and due to his having adopted a mistaken value for the *rati*. This view Mr. Ball is unable to accept. Nevertheless he considers it probable that the Koh-i-noor is the remnant of the Mogul diamond, from which portions have been removed while it was in the possession of the unfortunate grandson of Nadir Shah, or some other of those through whose hands it passed before it was acquired by Runjeet Singh; and that Baber's diamond was a distinct stone, now in the possession of the Shah of Persia, and known as the Dariya-i-noor (sea of lustre), the weight of which is also 186 carats.

Mr. Ball's careful criticism of the available evidence, and his clear setting forth of the several steps of his argument, give weight to the conclusion at which he finally arrives, that will doubtless be acknowledged even by those who differ from him. But as regards the identity of the Koh-i-noor and the Mogul diamond, there remains one objection which, as it appears to us, Mr. Ball has hardly adequately disposed of. If Tavernier's figure, as reproduced by Mr. Ball, represents at all faithfully the general form and especially the height of the Mogul diamond, it is difficult to see how a comparatively flat stone like the Koh-i-noor could have been obtained from it without a much greater reduction of its weight than the 82 carats which are all that his data admit of. The lateral dimensions of the two stones accord fairly enough, so that any reduction of Tavernier's figured stone, to bring it down to the required size, could be

effected only by diminishing its height; in which case it would hardly correspond to his description of its form as that of an egg cut in two. The question can only be fairly tested by the weighment of a model constructed as nearly as possible in accordance with Tavernier's figure, and of such lateral dimensions as to be capable of including the Koh-i-noor. It may be that such a model, of the specific gravity of the diamond, would be found much to exceed Tavernier's reported weight of the stone, in which case the importance of his figure as an item of evidence, would be greatly invalidated.

Whatever may be the final outcome of this controversy, Mr. Ball has done a good service to literature and science in re-translating Tavernier's work, in its careful editing, and in throwing light on much that has hitherto remained obscure. The result will certainly be that which he has anticipated, the vindication of Tavernier's claim "to be regarded as a veracious and original author."

H. F. B.

OUR BOOK SHELF.

Star Land. By Sir Robert S. Ball, LL.D., F.R.S. (London: Cassell and Co., 1889.)

THE author of this work is now so well known as a popular expounder of astronomical subjects that it is quite sufficient praise of his new book to say that it fully sustains his reputation. The book is described as "talks with young people about the wonders of the heavens," being founded chiefly on notes taken at his courses of juvenile lectures at the Royal Institution. Astronomy gives plenty of scope for the exercise of the imagination, and Dr. Ball takes full advantage of this. The book abounds with anecdotes and homely illustrations, calculated to impress the facts on the memory as well as to excite wonder at them. The startling figures dealt with in astronomy are, as usual, converted into railway train notation, and otherwise illustrated. One new illustration of the distances of the stars is that it would take all the Lancashire cotton factories 400 years to spin a thread long enough to reach the nearest star at the present rate of production of about 155,000,000 miles per day. The irregularities in the motion of Encke's comet are explained in an interesting dialogue between the "offending comet" and the astronomer, in which the comet explains that his delay was due to the fact that Mercury was "meddlesome."

The only disappointing parts of the book are those which deal with astronomical physics. One point not sufficiently insisted upon is the now generally acknowledged meteoritic constitution of comets; a connection is certainly suggested, but that comets are now supposed to be simply dense swarms of meteorites is not stated at all. Nebulæ, again, are described as "masses of glowing gas," notwithstanding the recent researches on the subject. The theory that meteorites are the products of ancient terrestrial volcanoes is also still adopted by Dr. Ball, without any consideration of the objections to such a view.

The book is well illustrated, and will undoubtedly awaken an interest in the subject in all intelligent readers.

The Magic Lantern: its Construction and Use. By a Fellow of the Chemical Society. (London: Perken, Son, and Rayment.)

THE third edition of this little book has been issued, and will be exceedingly useful to those who work with the lantern. Descriptions are given of the various lights used in lanterns, from the oil lamp to the electric arc; the methods of making simple slides are entered into, and a few experiments, illustrative of elementary scientific principles, are well included. The work is thoroughly practical; none of the little details so necessary to beginners have been omitted, whilst many of the hints it contains may be of service to all who use this optical instrument, whether it be for lecture purposes or for recreation only.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Acquired Characters and Congenital Variation.

I DO not see that the Duke of Argyll's last letter in any way strengthens his position. The questions at issue with regard to evolution are now, I believe, thoroughly understood by biologists. Nothing, in my opinion, can solve them in the direction the Duke desires but the evidence of fact. And that, I can only repeat, is precisely what is not forthcoming. I am equally of opinion that the discussion has been worn threadbare. I should not myself have interfered in it, had it not seemed desirable to show that the motives attributed by the Duke to those who accept Darwinian principles were destitute of foundation.

This part of his position the Duke does not attempt to defend. As to the rest he merely restates what he has said before. His remarks fall under two heads, and I shall content myself with the briefest possible comment upon these.

(1) *Acquired Characters.*—The Duke gives what I presume he intends as a logical proof of the theorem that acquired characters are inherited. It may, I think, be formally expressed as follows:—

"It is always possible to assert" that acquired characters are developed latent congenital characters.

It is admitted that congenital characters are inherited.

∴ Acquired characters are inherited.

It will be observed in the first place that this is a mere *a priori* argument. And next that, while it is not denied by Darwinians that the organism is a complex of congenital tendencies, limitations, and possibilities, this is entirely beside the question. From Lamarck to Darwin, Weismann, and Lankester, the meaning of "acquired characters" has been clearly defined. They are those changes of hypertrophy, extension, thickening, and the like, which are obviously due to the direct physical action of the environment on the body of the individual organism. It was these changes which Lamarck asserted were transmitted to the offspring; and it is this transmission which it is now maintained needs demonstration as a fact.

Let me give another illustration. I read the other day in the newspapers that the police of Paris have carried out an extremely interesting investigation. They have carefully ascertained the recognizable changes in the normal human organism produced by the prolonged pursuit of any particular occupation. The object was to obtain data for the identification of unknown dead bodies. The changes proved more numerous and characteristic than could have been supposed. They supplied, in fact, diagnostic marks by which the occupation of the individual could be accurately inferred. It seems to me impossible to have a more admirable case of the direct action of external conditions. I ask, Is there any reason to suppose that these acquired characters would be transmitted?

This appears to me an extremely plain issue, as it is certainly an extremely important one. There is not the least reluctance on the part of Darwinians to face it squarely. But the Duke appears to me to deliberately evade it.

(2) *Prophetic Germs.*—It seems to me that we are somewhat at cross-purposes. The Duke admits that I have correctly quoted him as saying: "All organs do actually pass through rudimentary stages in which actual use is impossible." When Prof. Lankester challenged the Duke to produce a single instance, he guarded himself by the remark: "The stages here alluded to are—if I understand correctly—ancestral stages, not stages in the embryological development of the individual." The Duke has never repudiated, as far as I am aware, that limitation of his meaning, if it be a limitation. And as he has

never responded to the challenge, I maintain that he has no right in a scientific discussion to reiterate a statement in support of which he has produced no definite observed evidence. He now returns the challenge to me. But it is no affair of mine. I simply take note of the fact that Prof. Lankester pointed out that the Duke's case collapsed unless the challenge was met, and that the Duke acquiesced by silence.

Just, however, as with the question of acquired characters, the Duke in defect of direct evidence now tries an *a priori* argument. He reminds us of the well known principle of embryology, sometimes called the recapitulation theory. Darwin states it in this form: the embryo is "a picture, more or less obscured, of the progenitor, either in its adult or larval state, of all the members of the same great class."

Now, of course, in the development of the individual organism, we have "a series of incipient structures on the rise for actual use," if by "on the rise" we mean in process of nutritive growth. This is, however, not necessarily true of the recapitulative structures which may or may not be temporarily utilized. When they are not so utilized they are mere survivals, and we know that survivals constantly so completely fall out of use, that by mere inspection it is often difficult to conceive what could have been their original function. I may give a single illustration. In flowering plants the homologue of the spore of the vascular cryptogams is still preserved. *Within* it, previous to fertilization, certain rudimentary structures are developed. It has been shown that these are the last recapitulative remnant of an independent series of structures developed *outside* the spore in the fern. In that type they form the prothallus, which possesses all the attributes of an independent organism, assimilates, respires, often reproduces itself asexually, and finally bears the sexual reproductive organs. All this in the flowering plant is not merely reduced to scarcely intelligible rudiments, but, in accordance with a well-known principle in embryology, it is thrown backwards in the order of development, and never emerges from the spore at all, instead of as in the fern being wholly external to and independent of it.

In this case we know the recapitulation and the thing recapitulated. We infer from their comparison that a fern-like plant was amongst the ancestry of the flowering plant. But I defy anyone, from a mere inspection of what happens in the latter, to form any idea of what happens in the former. From cases such as these it is obvious that the analogy between the development of the individual and the evolution of the race only holds for the broad facts of the sequence of stages, and does not give us any information as to the inutility of the structures of the ancestral organisms, or even, indeed, as to the precise period in their life when such structures made their appearance. The Duke's argument may now, I take it, be stated as follows:—

In the development of the individual organism, incipient organs are useless.

The development of the individual organism is a recapitulation of the evolution of the race.

∴ Incipient organs in the evolution of the race are useless.

I observe that the Duke's estimation of my logical powers is the reverse of flattering. I abstain, therefore, from criticizing this piece of reasoning. For my part I must confess I do not possess an *a priori* mind. No argument, however ingenious, is as convincing to me as accurately observed facts. If the Duke's convictions are laws of Nature, the objective verification ought to be forthcoming. W. T. THISELTON DYER.

Royal Gardens, Kew.

THE Duke of Argyll supports his assertion that "all organs do actually pass through rudimentary stages in which actual use is impossible" by reference to the stages of embryonic growth. Surely the assertion remains merely an empty repetition of the Darwinian position that the development of the embryo summarizes the morphological history of the race.

The modern dress coat has developed from a mere blanket, but even the useless parts of the modern coat can be easily shown to have had their use in some anterior forms of completed coat. The embryo, like the coat, preserves traces of evolutional stages at which what now appear useless characters were in reality actual useful characters.

What the Duke has to show is some instance of a completed organ in a completed organism, useless to that organism, not phases in the growth of an organ affording a blurred copy of some form of the organ existent at an anterior stage of the organism, and then useful to it. So far he has merely confounded ontogenal steps of growth with phylogenal phases of plan. F. V. DICKINS.

Burlington Gardens, February 3.

Eight Rainbows seen at the Same Time.

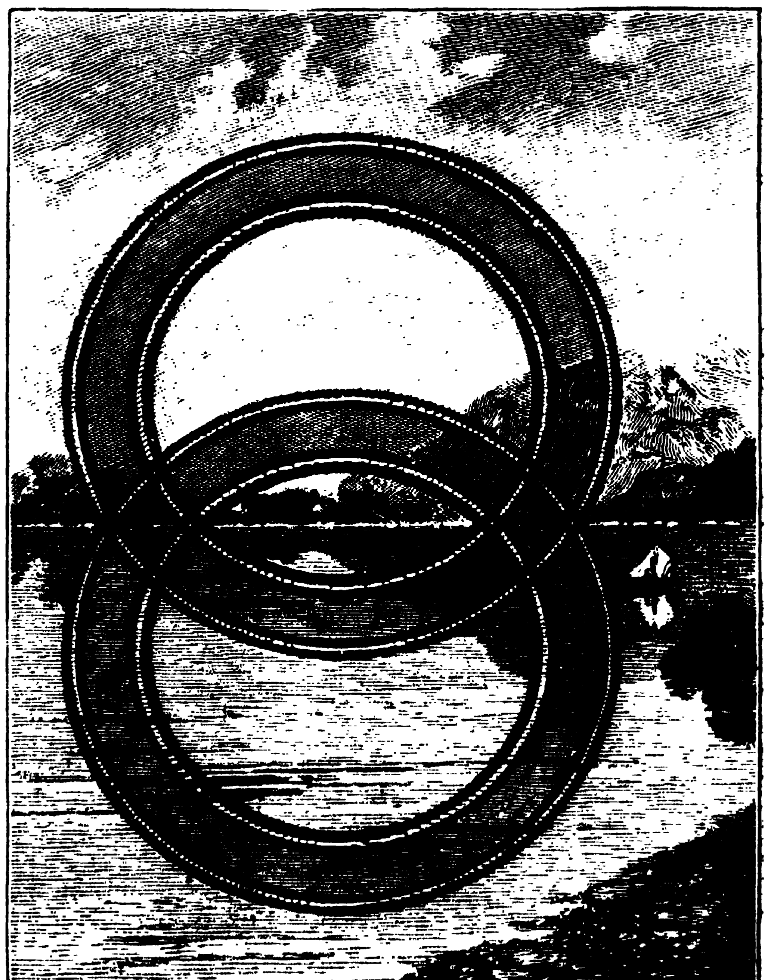
THE following letter which I have just received from Dr. Percival Frost of Cambridge, may interest your readers.

A statement that rainbows are produced not only by the sun itself directly, but by the image of the sun reflected from still water, is given in Prof. Tait's book on "Light." The phenomenon seems to have been observed by Halley in 1698 (see NATURE, vol. x. pp. 437, 460, and 483 for interesting correspondence on the subject).

The diffuse rainbow produced by the image of the sun reflected from a white cloud after sunset, described by Mr. Scouller, is, I believe, a novelty. WILLIAM THOMSON.

The University, Glasgow, January 31.

IN NATURE (January 23, p. 271) you give a letter from Mr. Scouller describing an interesting case of a rainbow, due to the image of the sun in water, which, with the ordinary, primary, and secondary bows, make up (there being no secondary to that formed by the reflected sun) the *three* which he saw. Here is a short account of what I saw long ago, almost in prehistoric times, in Scotland, where such sights ought, according to your correspondent, to be very commonly seen. I may mention that I saw at the same time, lasting some five minutes, *eight* well-defined rainbows of one sort or another.



In 1841, during the time of a long vacation party, spent at Oban, I walked out with my brother to Dunstaffnage, and we were on the top of the Castle, somewhere between 3 and 4 p.m., on a day in the middle of August. Not a breath of wind, bright sun over, I think, Lismore Lighthouse, dusky clouds all over Ben Cruachan and Conoll Ferry; the sea in the bay (bounded by Dunstaffnage in the west) as smooth as a pond. Gradually there appeared before us the astonishing sight of the aforesaid *eight* distinct rainbows, viz. primary and secondary ordinary bows; primary and secondary bows by reflected sun; primary and

secondary bows formed by light from the real sun reflected from the water after leaving certain drops; primary and secondary formed by light from the sun reflected at the water, and, after leaving certain other drops, again reflected at the water. I have called the latter four distinct bows, because, although they looked like reflections of a solid set of four arcs, they were really formed by means of drops distinct from those which helped to make the first four bows. I append a sketch of what I saw.

PERCIVAL FROST.

15 Fitzwilliam Street, January 29.

[We have received other letters on the subject of Mr. Scouller's letter.]

Thought and Breathing.

I SEND you some extracts from the Sanskrit Yoga-sûtras which treat very fully of the prâ*n*âyâma, or the expulsion and retention of breath, as a means of steadying the mind.

A Yogi has first of all to assume certain postures which help him to fix his mind on certain objects. He cannot concentrate his mind while walking or running. He ought to assume a firm and pleasant position, one requiring little effort. To judge, however, from the description given of some of these postures, they would seem to us anything but pleasant.

When a Yogi has accustomed himself to his posture, he begins to regulate his breath—that is, he draws in the breath through one nostril, retains it for some time in the chest, and then emits it through the other nostril. The details of this process are given in the first chapter of the Yoga-sûtras, sûtra 37. Here the commentator states that the expulsion means the throwing out of the air from the lungs in a fixed quantity through a special effort. Retention is the restraint or stoppage of the motion of breath for a certain limited time. That stoppage is effected by two acts—by filling the lungs with external air, and by retaining therein the inhaled air. Thus the threefold prâ*n*âyâma, including the three acts of expiration, inspiration, and retention of breath, fixes the thinking principle to one point of concentration. All the functions of the organs being preceded by that of the breath—there being always a correlation between breath and mind in their respective functions—the breath, when overcome by stopping all the functions of the organs, effects the concentration of the thinking principle to one object.

Rájendralal Mitra, to whom we owe a very valuable edition of the text and translation of the Yoga-sûtras, adds the following remarks:—"All other Yogic and Tantric works regard the three acts of expiration, inspiration, and retention performed in specific order to constitute prâ*n*âyâma. The order, however, is not always the same. . . . The mode of reckoning the time to be devoted to each act is regulated in one of two ways: (1) by so many repetitions of the syllable om, or the mystic mantra (formula) of the performer, or the specific mystic syllables (vîja) of that mantra; (2) by turning the thumb and the index-finger of the left hand round the left knee a given number of times. The time devoted to inspiration is the shortest, and to retention the longest. A Vaish*n*ava in his ordinary daily prayer repeats the Vîja-mantra once while expiring, 7 times while inspiring, and 20 times while retaining. A Sâkta repeats the mantra 16 times while inspiring, 64 times while retaining, and 32 times while expiring. These periods are frequently modified."

The usual mode of performing the prâ*n*âyâma is, after assuming the posture prescribed, to place the ring-finger of the right hand on the left nostril, pressing it so as to close it, and to expire with the right, then to press the right nostril with the thumb, and to inspire through the left nostril, and then to close the two nostrils with the ring finger and the thumb, and to stop all breathing. The order is reversed in the next operation, and in the third act the first form is required. The Ha*th*adîpikâ says:—"By the motion of the breath, the thinking principle moves; when that motion is stopped, it becomes motionless, and the Yogi becomes firm as the trunk of a tree; therefore the wind should be stopped. As long as the breath remains in the body, so long it is called living. Death is the exit of that breath, therefore it should be stopped."

Some of the minor works on Yoga expatiate on the sanitary and therapeutic advantages of practising prâ*n*âyâma regularly at stated times. In America some spiritualistic doctors prescribe the same practice for curing diseases.

In India prâ*n*âyâma is only a means towards a higher object—namely, the abstraction of the organs from their natural functions. It is a preliminary to Yoga, which consists in *dhâranâ*, steadfastness, *dhyâna*, contemplation, and *samâdhi*, meditation, or almost a cataleptic trance. These three are supposed to impart powers or *siddhis* which seem to us incredible, but which nevertheless are attested by the ancient Yogis in a very *bonâ-fide* spirit, and deserve examination, if only as instances of human credulity. I say nothing of modern impostures.

Oxford, January 22. F. MAX MÜLLER.

IN connection with Prof. Leumann's recent researches into the relation between changes in respiration and changes in certain cerebral functions, it seems curious that the employment of deep and rapid respiration as an anæsthetic has received so little attention. Some dentists order their patients to respire as quickly and fully as they can for a period which varies, I believe, from four to six minutes, although as to the exact duration I am insufficiently informed. At the termination of this period the patient becomes giddy, and to a great extent loses consciousness, when a short operation can be painlessly performed. The patient, while unable to move his arms, opens his mouth at the order of the operator. I have heard of no casualties or evil effects from this mode of treatment. W. CLEMENT LEY.

Chiff-Chaff singing in September.

DURING more than forty years' observation of the singing of birds, I have invariably heard the chiff-chaff singing in September, although the song is much less frequently repeated than in the spring. In connection with this observation I may mention that both the male and female birds appear to be always mute for two or three days after their spring arrival in Northern Europe. W. CLEMENT LEY.

Lutterworth, January 31.

Foreign Substances attached to Crabs.

I HAVE read in recent numbers of NATURE some letters on sponges attached to crabs.

There are two crabs on the east coast of Australia—one of them allied to *Dromia vulgaris*—which cover themselves with sponges or with a composite Ascidian. I have in one case counted no less than seven species of sponges on one individual crab.

The Ascidian referred to is usually from ten to thirty times as large as the crab to the back of which it is attached.

Among the specimens brought by me from Australia, and now deposited in the National Collection of the British Museum, there are some of these crabs with sponges and Ascidians attached.

These might, perhaps, be interesting to your correspondents on the subject. R. v. LENDENFELD.

University, Innsbruck, January 25.

Foot-Pounds.

"A. S. E." will find moments, of resistance, of bending, or of turning, expressed in foot-pounds (often inch-pounds or foot tons) in any treatise on civil, mechanical, or marine engineering, on architecture, land or naval, and, in fact, in every treatise on *real* mechanics he may consult. Why, then, should a different terminology be adopted in a Civil Service examination paper? In metric units, moments are given in kilogramme-metres or centimetres; but in the C.G.S. system I do not suppose it is suggested to measure moments of dyne-centimetres in ergs.

February 3. A. G. GREENHILL.

IF "A. S. E." will push his researches further, he will find that in Government dockyards the stability moment on ships is calculated in foot-tons. V.

PROF. WEISMANN'S THEORY OF HEREDITY.

IN NATURE of October 24, 1889 (p. 621), appeared a criticism by Prof. Vines of my essays on heredity and allied subjects. I should be glad to reply briefly to his objections, and the more so as I hope thus to be able to place the scientific problems at issue in a somewhat

clearer light. With regard to the immortality which I attribute both to the unicellular organisms and to the germinal cells of the multicellular, if I understand Prof. Vines aright, he does not attack the proposition itself, but has simply overlooked the explanation in my book of the way in which mortal organisms arose out of immortal in process of phyletic development, a process which must have taken place if the Protozoa have developed in the course of the world's history into the higher Metazoa,—"the first difficulty is to understand how the mortal heteroplastides can have been evolved from the immortal monoplastides." My explanation was simply that which appears to be the true one for the origin of every higher differentiation—namely, the division of the cell-mass of the Protozoan, on the principle of the division of labour, into two dissimilar halves, differing in substance, and consequently also in function; from the one cell which performed all functions comes a group of several cells which distribute themselves over the work. In my opinion, the first such differentiation produced two sets of cells, the one the mortal cells of the body proper, the other the immortal germ-cells. Prof. Vines certainly believes in the principle of the division of labour, and in the part that it has played in the development of the organic world, as well as I; but it seems to him that this division of a unicellular being into somatic and germinal cells is impossible, and that my explanation of the process by dissimilar division is inadequate, because it strikes him as "absurd to say that an immortal substance can be converted into a mortal substance."

There certainly does seem to be a great difficulty in this idea, but in reality it arises simply from a confusion of two conceptions—immortality and eternity. That the Protozoa and the germ-cells of Metazoa are in a certain sense immortal seems to me an incontrovertible proposition. As soon as one has clearly realized that the division of a monoplastid is in no way connected with the death of one part, there can be no further question that we have to do with individuals of indefinite duration; but this in no way implies that they possess an eternal duration; on the contrary, we imagine that they have all had a beginning. The conception of eternity, however, extends into the past as well as the future; it is without beginning or end, and does not affect the present question; it is an entirely artificial conception, and has no real and comprehensible existence; to express it more accurately, eternity is merely the negation of the conception of transitoriness. Of the objects with which natural science deals, none are eternal except the smallest particles of matter and their forces, certainly not the thousandfold semblances and combinations under which matter and force meet us. As I have said years ago, the immortality of unicellular organisms, and of the germ-cells of the multicellular, is not absolute but potential; it is not that they *must* live for ever as did the gods of the ancient Greeks—Ares received a "mortal" wound, and roared for pain like to ten thousand bulls, but could not die; they can die—the greater number do in fact die—but a proportion lives on which is of one and the same substance with the others. Does not life, here as elsewhere, depend on metabolism—that is to say, a constant change of material? And what is it, then, which is immortal? Clearly not the substance, but only a definite form of activity. The protoplasm of the unicellular animals is of such chemical and molecular structure that the cycle of material which constitutes life returns even to the same point and can always begin anew, so long as the necessary external conditions are forthcoming. It is like the circulation of water, which evaporates, gathers into clouds, and falls as rain upon the earth, always to evaporate afresh. And as in the physical and chemical properties of water there is no inherent cause for the cessation of this cycle, so there is no clear reason in the physical condition of unicellular organisms why the cycle of life, *i.e.* of division, growth by assimilation, and repeated division, should ever end; and this characteristic it is which I have termed immortality. It is the only true immortality to be found in Nature—a pure biological conception, and one to be carefully distinguished from the eternity of dead, that is to say unorganized, matter.

If then this true immortality is but cyclical, and is conditioned by the physical constitution of the protoplasm, why is it inconceivable that this constitution should be, under certain circumstances and to a certain extent, so modified that the metabolic activity no longer exactly follows its own orbit, but after more or fewer revolutions comes to a standstill and results in death? All living matter is variable; why should not variations in the protoplasm have also occurred which, while they fulfilled certain functions of the individual economy better, caused a metabolism which did not exactly repeat itself, *i.e.* sooner or later came to a condition of rest? I admit that I feel such a descent from immortality into mortality far less remarkable than the permanent retention of immortality by the monoplastids and germ-cells. Small, indeed, must be the variations in the complicated qualities of living matter to bring in their train such a fall; and very sharply must the essentials of its constitution be retained, for metabolism to take place so smoothly without creating in itself an obstacle to its own continuance! Even if we cannot penetrate into the mysteries of this constitution, still we may say that a rigorous and unceasing natural selection is unremittingly active in maintaining it at such an exact standard as to preserve its immortality; and every lapse from this standard is punished by death.

I believe that I have proved that organs no longer in use become rudimentary, and must finally disappear solely by "panmixie"; not through the direct action of disuse, but because natural selection no longer maintains their standard structure. What is true for an organ is true also for its function, since the latter is but the expression of the qualities of material parts, whether we can directly perceive their relations or not. If, then, as we saw, the immortality of monoplastids depends on the fact that the incessant metabolism of their bodies is ever returning exactly to its starting-point, and produces no such modifications as would gradually obstruct the repetition of the cycle, why should that quality of the living matter which causes immortality—nay, how *could* it be retained—when no longer necessary? It is obvious that it was no longer necessary in the somatic cells of the heteroplastids. From the instant that natural selection relaxed its watch on this quality of immortality began the process of panmixia which led to its abolition. Prof. Vines will ask, How can one conceive of this process? I answer, Quite easily. When once individuals arose among monoplastids, in the protoplasm of which occurred such variation in chemical and molecular constitution as to result in a gradual check on the metabolic cycle, it would happen that these individuals died; a permanent variety could not grow out of such variations. But if there arose among heteroplastids individuals with a similar differentiation of the somatic cells, the death of these cells would not be detrimental to the species, since its continuance is ensured by the immortal germ-cells. Upon the differentiation into germinal and somatic cells, natural selection was, speaking metaphorically, trained to bear on immortality of the germ-cells, but on quite other qualities in the somatic cells—on motility, irritability, capacity for assimilation, &c. We do not know whether the attainment of these qualities was accompanied by a constitutional alteration which caused the loss of immortality, but it is at least possible; and, if true, the somatic cells will have lost their immortality even more rapidly than through the unaided action of panmixia.

In the fourth essay of my book, I have cited the two Volvocinean genera Pandorina and Volvox as examples

of the differentiation of homoplastids into the lowest heteroplastids; in Pandorina the cells are still all alike and all perform the same functions, in Volvox occur somatic and germinal cells, and in the latter case we should expect to find the commencement of natural death Recent researches of Dr. Klein ("Morphologische und biologische Studien über die Gattung Volvox," *Jahrb. wiss. Botan.*, xx., 1889) show that this is actually the case; as soon as the germ-cells are ripe and emerge from the sphere, the ciliated somatic cells begin to shrivel up, and die in one or two days. This is the more interesting, as the somatic are also the nutritive cells; for, though the germ-cells also possess chlorophyll, the rapid growth of the latter (which attain an enormous size in Volvox) is only possible by the supply of nourishment from the somatic cells. The latter are so constituted that they assimilate, but cannot grow larger when once the sphere has reached its definite size; they transfer the nourishment which they derive from the decomposition of carbon dioxide, &c., to the germinal cells by means of fine pseudopodia; and themselves wither when once the germs are ripe. In this case adaptation to the nutrition of the germinal cells might well have accelerated the introduction of a natural death of the somatic cells, the capacity for considerable assimilation combined with a drain on their nutrition may have led after a certain time to stoppage of the process of assimilation and to death. To me, the idea that modification of the living matter may have been connected with loss of immortality does not appear more unlikely or more difficult than the generally received view of the gradual differentiation of the somatic cells in the course of phylogeny into their various species of digestive, secretive, motile, and nervous cells. An immortal unalterable living substance does not exist, but only immortal *forms of activity* of organized matter.

I maintain, therefore, in its entirety, my original statement, that monoplastids and the germ-cells of higher forms have no natural death. I do not know how this can to-day be better expressed than by saying that these living units possess a real and actual immortality as against the imaginary ideal immortality of the Greek gods. If death from internal causes does not exist for them, one may yet say with certainty that the fatal hour will one day strike for them all, not from internal causes, but because the external conditions for the constant renewal of vital activity will some day cease. The physicists prophesy that the circulation of water on the globe will end, not from any alteration in the qualities of water, but because external conditions will render this form of motion of aqueous particles impossible.

Prof. Vines then attacks my view of embryogeny. He finds it "not a little remarkable that Prof. Weismann should not have offered any suggestion as to the conception which he has formed of the mode in which the conversion of germ-plasm into somatoplasm can take place, considering that this assumption is the key to his whole position." He sees here the same difficulty as in the phyletic development, and says: "There is really no other criticism to be made on an unsupported assumption such as this, than to say that it involves a contradiction in terms." He means by this that the eternal cannot pass into the finite, as must be the case if the immortal germ-cell grow into the mortal soma. At the bottom of this objection lies the same confusion between immortality and eternity which has already been made clear. I do not wish to reproach Prof. Vines with this obscurity, as I felt the same objection myself for many years, and could not at once discover the reply to it; on the contrary, I am indebted to him for the opportunity to express myself on the point. Up to this time we have had no scientific conception of immortality; if this be accepted, the significance of immortality is not life without beginning or end, but life which, after its first commencement, can continue indefinitely with or without modification (specific changes in the germ-plasm or the monoplastids); it is a cyclical activity of organic material devoid of any intrinsic momentum which would lead to its cessation, just as the motion of the planets contains no intrinsic momentum which would lead to its cessation, although it has had a commencement and will some day, through the operation of extrinsic forces, have an end.

Prof. Vines says later: "I understand Prof. Weismann to imply that his theory of heredity is not—like, for instance, Darwin's theory of pangenesis—a provisional or purely formal solution of the question, but one which is applicable to every detail of embryogeny, as well as to the more general phenomena of heredity and variation." I have, as a matter of fact, designated Darwin's pangenesis as a "purely formal" solution of the question, but should like here to give a slight explanation of the expression, as I fear that not only Prof. Vines, but also many other readers of my essays, have misunderstood me. On the one hand, I am afraid that they see in my words a definite reproach against Darwin for his theory of pangenesis, of which I had not the remotest intention; and on the other, that they incline to charge me with too great an affection for my own theory.

I believe there are two kinds of theory; one may term them the "real" and the "ideal"; practically they are rarely sharply to be discriminated; both often occur in one and the same theory, but should be conceived of separately. The "ideal" theories attempt to render conceivable the phenomena to be explained by an arbitrarily accepted principle, apart from the question whether the principle itself possesses any grain of truth or not; they seek only to show that there are hypotheses on which the phenomena in question become comprehensible. "Real" theories do not make hypotheses at pleasure, but strive to construct such as have some degree of probability; they desire to give not a formal, but, if possible, the right explanation. Sir William Thomson in endeavouring to make clear the dispersion of rays of light, never believed in the remotest degree that such molecules as he pictured really existed, but desired merely to show that there were hypotheses on which the phenomena of dispersion were comprehensible. Darwin's pangenesis was originally intended in this sense, and was by him termed a "provisional" hypothesis, although in later years he may have attributed to it the weight of a real theory. To me his "gemmules" are a pure invention, an invention in no way corresponding to the actual facts, but showing what hypotheses must be made in order to explain the phenomena of heredity. Are, however, such ideal theories worthless? Certainly not. They are often the first and essential step towards the understanding of complicated phenomena, and lay the foundation for the gradual erection of a real theory. It would perhaps never have occurred to me to deny the inheritance of acquired characters, had not Darwin's pangenesis shown me that the matter was only explicable on an hypothesis so difficult to conceive, as that of the giving off, circulation, and reassemblage of gemmules. I do not even now maintain that Darwin's pangenesis cannot possibly contain a kernel of truth; De Vries ("Intracellulare Pangenesis," Jena, 1889) has shown in a recent and most interesting memoir that the ideal impossible pangenesis may be transformed into a real and possible one by means of certain profound modifications; he accepts my view that acquired (somatogenic) modifications cannot be transmitted, and thereby puts on one side just that part of Darwin's theory which has always appeared to me to lie beyond the pale of reality—namely, the circulation, &c., of the gemmules. The future will show whether his view of modified gemmules or my hypothesis is the best explanation of the facts of heredity.

In any case, I am far from assuming that I have settled the whole question of heredity; I have undertaken researches on some of the more important parts of the

problem, and have thus been compelled to formulate some fundamental principles for the explanation of the phenomena; but no one can be more convinced than I how far we are from a definite and complete explanation, not only of "every detail," but also of "the more general phenomena." My endeavour was to put forth a real, in place of the previous ideal, theory; and on this ground I took pains to make only such suppositions as might possibly correspond to actual facts. There certainly is a material carrier of heredity in the ovum; it certainly can be transported from nucleus to nucleus; it certainly can be modified in the process, or can remain the same; and even the supposition that it is able to stamp its own character on the cell contains nothing which seems to us impossible and non-existent; on the contrary, we are able now to state that it is so, even if we do not understand in what wise it happens. My hypothesis relative to the quiescent state of germ-plasma also rests on a basis of fact; we know that ancestral characteristics may be transmitted in a latent condition, and that the process of transmission is bound up with a substance, the idioplasma; there must therefore actually be an inactive stage of idioplasma.

If it could be shown that upon such principles an explanation of heredity is attainable, we should have made a distinct advance upon the ideal theory of pangenesis which is founded on unreal hypotheses. Possibly it is upon the path which I have opened up that we shall gradually attain a satisfactory solution of the numerous questions at issue; possibly further research will show that it is not the right path, and must be abandoned; no one, it appears to me, can foretell this. My reflections on heredity are not a conclusion, but a commencement—no complete theory of heredity which claims to provide a complete solution of all the problems at issue, but *researches* which, if fortunate, may sooner or later, by direct or circuitous paths, lead to a true appreciation of the question, to a "real" theory. In the preface to the English edition of my "Essays" I have stated this expressly.

I have also in that place distinctly insisted that the book was not written as a whole; that it consists rather of a series of researches, the one growing out of the other, and showing the development of my views as they shaped themselves during the course of nearly a decade's work. It is therefore unreasonable to extract ideas from an earlier essay and apply them against a later one. I have left them unaltered, and even "left certain errors of interpretation uncorrected," because, if altered, their internal connection could not have been understood.

I believe that the objections which Prof. Vines makes to my theory of the continuity of germ-plasma rest solely on an unintentional confusion of my ideas, as he compares the opinions expressed in the second essay with those of the later ones, with which they do not tally. I will endeavour to make this clear. In this second essay (1883) I contrasted the body (soma) with the germ-cells, and explained heredity by the hypothesis of a "Vererbungs-substanz" in the germ cells (in fact the germ-plasma), which is transmitted without breach of continuity from one generation to the next. I was not then aware that this lay only in the nucleus of the ovum, and could therefore contrast the entire substance of the ovum with the substance of the body-cells, and term the latter "somatoplasm." In Essay IV. (1885) I had arrived, like Strasburger and O. Hertwig, at the conviction that the nuclear substance, the chromatin of the nuclear loops, was the carrier of heredity, and that the body of the cell was nutritive but not formative. Like the investigators just named, I transferred the conception of idioplasma, which Nägeli had enunciated in essentially different terms, to the "Vererbungs-substanz" of the ovum-nucleus, and laid down that the nuclear chromatin was the idioplasma not only of the ovum but of every cell, that it was the dominant cell-element which impressed its specific character upon the originally indifferent cell-mass. From then onwards, I no longer designated the cells of the body simply as "somatoplasm," but distinguished, on the one hand, the idioplasm or "Anlagen-plasma" of the nucleus from the cell-body or "Cytoplasma," and, on the other, the idioplasm of the ovum-nucleus from that of the somatic cell-nucleus; I also for the future applied "germ-plasm" to the nuclear idioplasm of ovum and spermatozoon, and "somatic idioplasm" to that of the body-cells (*e.g.* p. 184). The embryogenesis rests, according to my idea, on alterations in the nuclear idioplasma of the ovum, or "germ-plasm"; on p. 186, *et seqq.*, is pictured the way in which the nuclear idioplasm is halved in the first cell-division, undergoing regular alterations of its substance in such a way that neither half contains all the hereditary tendencies, but the one daughter-nucleus has those of the ectoblast, the other those of the entoblast; the whole remaining embryogenesis rests on a continuation of this process of regular alterations of the idioplasma. Each fresh cell-division sorts out tendencies which were mixed in the nucleus of the mother-cell, until the complete mass of embryonic cells is formed, each with a nuclear idioplasm which stamps its specific histological character on the cell.

I really do not understand how Prof. Vines can find such remarkable difficulties in this idea. The appearance of the sexual cells generally occurs late in the embryogeny; in order, then, to preserve the continuity of germ-plasm from one generation to the next, I propound the hypothesis that in segmentation it is not *all* the germ-plasm (*i.e.* idioplasm of the first ontogenetic grade) which is transformed into the second grade, but that a minute portion remains unaltered in one of the daughter-cells, mingled with its nuclear idioplasm, but in an inactive state; and that it traverses in this manner a longer or shorter series of cells, till, reaching those cells on which it stamps the character of germinal cells, it at last assumes the active state. This hypothesis is not purely gratuitous, but is supported by observations, notably by the remarkable wanderings of the germinal cells of Hydroids from their original positions.

But let us neglect the probability of my hypothesis, and consider merely its logical accuracy. Prof. Vines says:—"The fate of the germ-plasm of the fertilized ovum is, according to Prof. Weismann, to be converted in part into the somatoplasm [!] of the embryo, and in part to be stored up in the germ-cells of the embryo. This being so, how are we to conceive that the germ-plasm of the ovum can impress upon the somatoplasm [!] of the developing embryo the hereditary character of which it (the germ-plasm) is the bearer? This function cannot be discharged by that portion of the germ-plasm of the ovum which has become converted into the somatoplasm [!] of the embryo *for the simple reason that it has ceased to be germ-plasm*, and must therefore have lost the properties characteristic of that substance. Neither can it be discharged by that portion of the germ-plasm of the ovum which is aggregated in the germ-cells of the embryo, for under these circumstances, it is withdrawn from all direct relation with the developing somatic cells. The question remains without an answer." I believe myself to have answered this above. I do not recognize the somatoplasm of Prof. Vines; my germ-plasm or idioplasm of the first ontogenetic grade is not modified into the somatoplasm of Prof. Vines, but into idioplasm of the second, third, fourth, hundredth, &c., grade, and every one impresses its character on the cell containing it.

Prof. Vines also attacks my view of the idioplasmatic nature of the *nuclear* substance (the chromatic grains); and maintains that it is as easy to speak of the continuity of the cell-body as of that of the nuclear substance, and that the one may transmit heritable qualities to progeny as well as the other. I quite understand that a botanist may easily be led to this view; and Prof. Vines is not the

only one to hold it. Waldeyer (" Ueber Karyokinese und ihre Beziehung zu den Befruchtungs-vorgänge," *Arch. mikr. Anat.*, xxxii., 1888) has considered the observed facts insufficient to justify the regarding of the nuclear loops as idioplasm ; Whitman (" The Seat of Formative and Regenerative Energy," Boston, 1888) among zoologists has expressed himself against this view, and the same occurs in the recent book of Geddes and Thomson (" The Evolution of Sex," London, 1889). The facts which led me to the idea that the nuclear threads were the real carriers of heredity—were, in fact, the idioplasma—are enumerated in Essay IV. ; they were primarily the observations of E. van Beneden on the phenomena of fertilization in the ovum of *Ascaria megalocephala*, those of Strasburger on fertilization in the Phanerogams by a mere nucleus, and the researches of Nussbaum and Gruber on division in the Infusoria. One may further cite as of essential importance the facts of karyokinesis *per se*, and the circumstance that, only on the supposition that the nucleus contains the idioplasma can the extrusion of polar bodies from the animal ovum be rendered comprehensible. The latter process divides the nuclear substance of the ovum into two quantitatively equal halves, but the body of the ovum into two unequal halves, the size of which is different in every species. The essential part of the process must therefore be the division of the nuclear substance, not that of the cell-mass. These facts on reflection so completely convinced me that the nucleus alone acts as carrier of hereditary tendencies, that the theory of the physiological equality of the nuclei of the sexual elements which I had propounded ten years before (1873) struck me as a certainty ; and I then advanced the theory of fertilization which is contained on p. 246 of Essay IV. I believe that till recently Strasburger and I alone had expressed similar views of the essence of fertilization, at least so far as relates to the homodynamy of the sexual nuclei. That most distinguished observer, E. van Beneden, who has won such renown in the investigation of the process of fertilization, took his stand with regard to its theoretical significance on the platform of the older view, which regarded it as the union of two elements intrinsically and essentially the opposite of each other. He could not free himself from that dominant and deeply rooted idea, that the difference between the sexes is something fundamental, an essential principle of existence. The fertilized oosperm is in his eyes a hermaphrodite object, uniting in itself both male and female essences, an idea in which many other observers (cf. Kölliker, " Die Bedeutung der Zellenkerne für die Vorgänge der Vererbung," *Zeit. wiss. Zool.*, xlii., 1885) have followed him, and of which the logical sequence is that all the cells of the body are to be regarded as hermaphrodite !

Van Beneden was also influenced by the idea which sways the naturalists of so many countries, that fertilization is a process of rejuvenescence, in the sense that without it life cannot be prolonged to the end. Many still hold to this idea ; Maupas (" Recherches expér. sur la multiplication des infusoires ciliés," *Arch. zool. exp. gén.*, (2) vi. p. 165) very recently believed that he had found a proof of its correctness, and attempted to show that Infusoria, for a continuance of existence, must from time to time enter into conjugation, or die from internal causes if this conjugation be prevented. Even were his observations correct, they would still fall short of proving his conclusions ; they would prove nothing against the immortality of the Protozoa, or for a rejuvenescence in the sense here intended ; they would rather state the platitude that ovum and spermatozoon must die, if the condition of their continued existence, namely fusion, inevitable in most species of plants and animals, be prohibited ; but this is an accidental, not a natural, death. Richard Hertwig (" Ueber die Conjugation der Infusorien," München, 1889) has also briefly shown that the facts, on which Maupas bases his inference, are not universally true ; that Infusoria hindered from conjugation do not die, but increase by division, and may produce whole colonies of animals—nay, that they are generally thus rendered abnormally prolific.

I am distinctly opposed to the rejuvenescence theory, whether applied to unicellular or multicellular organisms ; my view is expressed in Essay IV., and may be summarized in this position—we should no longer speak of the conjugating nuclei of the sexual elements as male and female, but as *paternal* and *maternal*, there is no opposition of the one to the other, they are essentially alike, and differ only so far as one individual differs from another of the same species. Fertilization is no process of rejuvenescence, but merely a union of the hereditary tendencies of two individuals ; tendencies which are bound up with the matter of the nuclear loops ; the cell-body of the ovum and spermatozoon is indifferent in this connection, and plays merely the part of a nutritive matter which is modified and shaped by the dominant idioplasm of the nucleus in a definite way, as clay in the sculptor's hand. The different appearance and function of ovum and spermatozoon, and their mutual attraction, rest on secondary adaptations, qualified to ensure that they shall meet and that their idioplasmata shall come into contact, &c. ; and as with the cells, so the differentiation of *persons* into male and female is also secondary ; all the numerous differences of form and function which characterize sex in the higher animals, the so-called " secondary sexual characters," which reach even into the highest spiritual regions of mankind, are nothing but adaptations to ensure the union of the hereditary tendencies of two individuals.

These are briefly the views of fertilization which I have indicated since 1873, but have only published in a finished and definite shape since the discovery by van Beneden of the morphological processes in the fertilization of the ovum of Ascaris (Essay IV., 1885). I concluded then with these words :—" If it were possible to introduce the female pro-nucleus of an egg into another egg of the same species, immediately after the transformation of the latter into the female pro-nucleus, it is very probable that the two nuclei would conjugate just as if a fertilizing sperm-nucleus had penetrated [the ovum]. If this were so, the direct proof that egg-nucleus and sperm-nucleus are identical would be furnished. Unfortunately the practical difficulties are so great that it is hardly possible that the experiment can ever be made ; but such want of experimental proof is partially compensated by the fact, ascertained by Berthold, that in certain Algæ (Ectocarpus and Scytosiphon) there is not only a female, but also a male parthenogenesis ; for he shows that in these species the male germ-cells may sometimes develop into plants, which however are very weakly."

I have since attempted to fertilize one frog's egg with the nucleus of another ; the experiment was, as one would expect, not successful, owing to the enormous havoc caused by introducing a cannula into the egg ; but Boveri (" Ein geschlechtlich erzeugter Organismus ohne mütterliche Eigenschaften," *Ges. Morph. Physiol. München*, 16 Juli, 1889) was more fortunate, in finding an object which allowed of the converse experiment to mine ; following Hertwig's example, he removed the nucleus from an Echinoid ovum by agitation, and brought such denucleated ova to develop by introducing spermatozoa. From the spermatozoan nucleus was formed a regular segmentation-nucleus, the embryogenesis pursued its regular course, and there was formed a complete though small free-swimming larva, which lived for a week. From this experiment alone it follows that the views of Strasburger and myself on fertilization are correct, *viz.* that the sperm-nucleus can play the part of ovum-nucleus and *vice versâ*, and the older view, to which Prof. Vines (" Lectures on the Physiology of Plants," Cambridge, 1886, pp. 638-681) has also sworn allegiance, must be given up.

An interesting and important modification of Boveri's experiment confirmed both this experiment, and also, if it were necessary, the recognition of the nuclear substance as idioplasm, as maintained by O. Hertwig, Strasburger, and myself. If eggs of *Echinus microtuberculatus*, when artificially deprived of their nuclei, be fertilized with the spermatozoa of *Sphærechinus granulatus*, *larvæ are developed with the true characters of the second species*—that is to say, they have derived everything from the father, nothing from the mother; the nuclear substance alone it is which transmits heredity, and by it the cell-mass is dominated.

I have interpreted the first polar body of the Metazoan ovum as a carrier of ovogenous plasm, which has to be removed from the ovum in order that the germ-plasm may attain the predominance. It is possible that this explanation is not correct; the most recent researches on the conjugation of Infusoria, as expressed in the splendid memoirs of Maupas and R. Hertwig, argue against my interpretation; but the idea which lay at the bottom of this explanation is justified. As it is the nuclear matter which gives to the cell-body its specific character, the ovum must, previous to fertilization, be dominated by a different idioplasm to the sperm-cell, since they are, up to this point, different in appearance and function. On the other hand, when they have united, they contain the same idioplasm—namely, germ-plasm; the consequence is that the first dominant idioplasm is different to that of a later period. This was the idea at the bottom of my explanation of the first polar body, and it is correct. One might perhaps imagine that the idioplasmata of ovum and spermatozoon were originally different, but that both possessed the power of alteration into germ-plasm; but it would be then incomprehensible why parthenogenetic ova should expel one polar body. Both facts, however, are explicable, if ovum and spermatozoon are dominated up to the period of maturation by different histogenetic idioplasmata with which a small quantity of germ-plasm is mingled, and if at a later period the former be removed and the germ-plasm come to rule in both cells. This process would be by no means abnormal and unparalleled, since entirely analogous divisions of the idioplasm into qualitatively dissimilar portions must occur hundreds of times in every embryogenesis. However, I am most willing to allow that the last word has not yet been said on this question, and would only maintain that my theory of heredity is not concerned thereby. It is not the interpretation of the first polar body, but that of the second, which is decisive; and one can none the less easily think of the latter as a halving of the number of ancestral germ-plasmata, even if it be proved that my explanation of the first polar body was erroneous. I would then express the first division merely as introductory to the second, as the necessary first step in the reduction of ancestral plasmata, the necessity for which we should thus perhaps learn to understand.

The regular modification of idioplasma during the ontogeny, which I have maintained and which so many have attacked (Kölliker[1] with special vehemence) will now stand out as justified. If the nucleus of a sperm-cell is capable of impressing on the denucleated mass of an ovum its own inherited tendencies, and of calling into being an organism with specific characteristics purely paternal, it will be found difficult to explain the ontogeny otherwise than as a regular modification of the idioplasm, continuous from one cell-division to another, which stamps on the body of each separate cell at each stage its peculiar character, not only with regard to shape but also to function, and especially with regard to the "rhythm" of cell-division.

[1] "Das Karyoplasma und die Vererbung: eine Kritik der Weismann'sche Theorie von der Continuität des Keimplasma's," *Zeit. wiss. Zool.*, xliv. p. 228, 1886.

A further objection is directed by Prof. Vines against my views on the origin of variation. In the fifth essay I have sought the significance of sexual reproduction in the fact that it alone could have called into existence that multiplicity of form of the higher animals and plants, and that constantly fluctuating union of individual variations, of which natural selection stood in need for the creation of new species. I am still of the opinion that the origin of sexual reproduction depends on the advantage which it affords to the operation of natural selection; nay, I am completely convinced that only through its introduction was the higher development of the organic world possible. Still, I am at present inclined to believe that Prof. Vines is correct in questioning whether sexual reproduction is the *only* factor which maintains Metazoa and Metaphyta in a state of variability. I could have pointed out in the English edition of my "Essays" that my views on this point had altered since their publication; my friend Prof. de Bary, too early lost to science, had already called my attention to those parthenogenetic Fungi which Prof. Vines justly cites against my views; but I desired, on grounds already mentioned, to undertake no alteration in the essays. Besides, I was well aware when the essay was first committed to paper (1886) that my current view on the radical cause of variation was possibly incomplete; and so, in order to expose the truth of the view as far as possible to a general test, I drove its logical consequences home, and enunciated the statement that species reproducing parthenogenetically could not be modified into new species. I also began myself at that time experiments on the variation of parthenogenetic species which are still being continued, and on which on some future occasion I hope to be able to report.

Even if, however, from our present knowledge it is probable that sexual reproduction is not the sole radical cause of variability of the Metazoa, still no one will dispute that it is a most active means of heightening variations and of mingling them in favourable proportions. I believe that the important part which this method of reproduction has played in calling out the existing processes of selection, is hardly diminished, even if one grants that direct influences upon the idioplasm call forth a portion of individual variability. Prof. Vines even holds it probable "that the absence of sexuality in these plants [Fungi] may be just the reason why no higher forms have been evolved from them, for in this respect they present a striking contrast to the higher Algæ in which sexuality is well marked." But when Prof. Vines says, "there can be no doubt that sexual reproduction does very materially promote variation," he does not mean to say that this is a self-evident proposition; he is well aware that prominent investigators like Strasburger see in sexual reproduction the reverse action, that of maintaining the constancy of the specific character. But I gladly accept his agreement with my view, which confirms the main position of the fifth essay, which runs: Sexual reproduction has arisen by and for natural selection as the sole means by which individual variations can be united and combined in every possible proportion.

With reference also to the problem of the inheritance of acquired (somatogenic) characters, Prof. Vines is again my opponent; he holds that such inheritance is possible. I have denied it, because it did not appear to me self-evident—as was formerly universally assumed—but rather utterly unproven; and because I think that completely unfounded assumptions of such far-reaching consequence should not be made, when requiring a large number of improbable hypotheses for their explication. I have tested all the available evidence for such inheritance as accurately as I could, and have found that none has the value of proof. There is no inheritance of mutilations, and this constitutes up to now the only basis of fact for the supposition of the inheritance of somatogenic variations. If, in the last essay, I have not denied every

possibility of such a transmission, Prof. Vines should interpret that in my favour, not to my discredit; it is not the business of an investigator to set forth a proposition, which on the existing evidence he is compelled to believe, as an infallible dogma. Prof. Vines finds my "statements of opinion so fluctuating that it is difficult to determine what [my] position exactly is," but he could have easily discovered my meaning, if, instead of promiscuously contrasting the eight essays and the eight years of their production, he had merely brought the last of them to the bar of judgment. This essay is especially concerned with "the supposed transmission of mutilations," and at its conclusion my verdict on the state of the problem of the inheritance of acquired characters is thus summarised:—"The true decision as to the Lamarckian principle [lies in] the explanation of the observed phenomena of transformation. . . . If, as I believe, these phenomena can be explained without the Lamarckian principle, we have no right to assume a form of transmission of which we cannot prove the existence. Only if it could be shown that we cannot now or ever dispense with the principle, should we be justified in accepting it." The distinguished botanist De Vries has proved that certain constituents of the cell-body, *e.g.* the chromatophores of Algæ, pass directly from the maternal ovum to the daughter-organism, while the male germ-cell generally contains no chromatophores. Here it appears possible that a transmission of somatogenic variation has occurred; in these lower plants, the separation between somatic and reproductive cells is slight, and the body of the ovum does not require a complete chemical and physical alteration to become the body of the somatic cell of the daughter. But how does this affect the question whether, for instance, a pianoforte player can transmit to his progeny that strength of his finger-muscles which he has acquired by practice? How does this result of practice arrive at the germ-cells? In that lies the real problem which those have to solve who maintain that somatogenic characters are transmissible.

It is proved by the observations of Boveri, quoted above, that among animals the body of the ovum contributes nothing to inheritance. If the transmission of acquired characters should take place, it would have to be by means of the nuclear matter of the germ-cells—in fact, by the germ-plasm, and that not in its patent, but in its latent condition.

To renounce the principle of Lamarck is certainly not the way to facilitate the explanation of the phenomena; but we require, not a mere formal explanation of the origin of species of the most comfortable nature, but the real and rightful explanation. We must attempt, therefore, to elucidate the phenomena without the aid of this principle, and I believe myself to have made a beginning in this direction. A short time ago I tried this in one of those cases where one would least expect to be able to dispense with the principle of modification by use—namely, in the question of artistic endowment.[1] I proposed to myself the question whether the musical sense of mankind could be conceived of as arising without a heightening of the original acoustic faculty by use. But even here I came to the conclusion that, not only do we not need this principle, but that use has actually taken no part in the development of the musical sense.

A. WEISMANN.

THE LIFE AND WORK OF G. A. HIRN.

THE three men who worked at the experimental determination of the mechanical equivalent of heat and at practical Thermodynamics have passed away within a few months of each other—Clausius, Joule, and now Hirn.

[1] "Gedanken über Musik bei Thieren und bei Menschen," *Deutsche Rundschau*, October 1889.

They were much of the same age, and began their experiments while young at almost the same time; and the practical agreement of the conclusions drawn from their experimental results is our best guarantee of confidence in the modern theory of Thermodynamics which is built upon these results.

Gustave Adolphe Hirn was born at Logelbach, in Alsace, on August 21, 1815, and died on January 14 of this year, a victim to the prevailing epidemic of influenza; but for this, we might have expected still further developments of his scientific theories, as he continued at work on his favourite subjects to the last.

Self-taught, so far as his scientific education was concerned, he found himself, with his elder brother Ferdinand, a manager of the works of Haussman, Jordan, and Co., an establishment for the fabrication of *indiennes*, established in 1772. Finding the machinery antiquated and worn out, Hirn, in setting to work to make the best of it, was really better placed for theorizing and experimentalizing than if he had charge of modern works in first-rate order. The different parts of the works being at a distance from each other, his brother Ferdinand brought out his system of cable transmission of power; and it was Gustave who pointed out theoretically the advantage of a thin light cable run at a high speed.

Hirn also turned his attention to the important economic question of the lubrication of machinery, and upset the previous prejudice against the use of mineral oil for this purpose. He also demonstrated experimentally that, while the old laws of friction enunciated by Morin were sufficiently accurate for the contact of one dry metal against another, these laws are powerfully modified when the surfaces are well lubricated, as with machinery. Now the friction varies as the square root of the pressure, and as the surface and the velocity; so that the theory falls in with that of the viscous flow of liquids. These laws have received confirmation of recent years by the experiments carried out under the auspices of the Institution of Mechanical Engineers.

But it is chiefly for his experiments on a large scale on the steam-engines under his charge that Hirn is best known, and from his varied methods of determining the mechanical equivalent of heat by the friction of metals on metal or water, and finally from observation of the amount of heat consumed by the steam-engine, when every source of gain or loss is carefully followed up.

With this object he investigated experimentally the separate effects of conduction, of jacketing, of initial condensation in the cylinder, and of its prevention by superheating.

If we watch the performance of a modern marine triple-expansion engine, we notice that the high-pressure cylinder appears choked with water from initial condensation, while the intermediate and low-pressure cylinders work comparatively dry. It was considered in the early days of compound engines that this initial condensation was a source of great loss, and superheating was introduced to minimize it. But the superheated steam ruined the packings, and dried up the lubricant, so that the superheater was found practically to do more harm than good. A characteristic story is told of John Elder, the pioneer of compounding in modern marine engines, too long to insert here, which bears on this point.

Nowadays this initial condensation is looked upon as inevitable, and as not really so uneconomical as the books make out, when attendant advantages are considered; but to the theorist such as Hirn this condensation was something to be avoided at any cost, and he worked hard to make its prevention feasible.

Hirn was a man of varied reading, taste, and pursuits, and he worked into his treatises on his favourite subject of Thermodynamics a good deal of speculative metaphysics, which make his books rather curious reading sometimes to modern tastes, and we must go back to the

time of Descartes and Leibnitz, when physical science and moral philosophy went hand in hand, to find an equivalent.

But it must be allowed that the science of Thermodynamics may be treated with advantage from this double point of view; for, after its First Law has been established, that heat and work are equivalent and interchangeable, the rate of exchange being fixed by the mechanical equivalent of Joule and Hirn, when we come to the Second Law, named after Carnot, we are compelled to secure conviction of its truth by an appeal to the arguments of analogy and metaphysics.

Hirn spent the last years of his life at Colmar, in the society of a few congenial friends, much interested in metaphysics and meteorology, but cut off from his native France by international strained relations.

In this age of practical Thermodynamics his work will not be lost sight of; but we are still far from a complete reconciliation of the abstract theories of the books and the observed realities of practice.

A. G. GREENHILL.

NOTES.

THE Croonian Lecture, which will be delivered before the Royal Society on February 27 by Prof. Marshall Ward, will be on "The Relations between Host and Parasite in certain Epidemic Diseases of Plants."

ON Thursday last the Astronomer-Royal was elected by ballot to fill the place of the late Father Perry upon the Council of the Royal Society.

METEOROLOGISTS will be sorry to hear of the death of Prof. C. H. D. Buys-Ballot, on Sunday last. He was born in 1817, and had been Director of the Meteorological Institute, Utrecht, for more than 30 years.

DR. DAVID SHARP, the eminent entomologist, and late President of the Entomological Society of London, has accepted the appointment of Curator in Zoology in the Museum of the University of Cambridge, rendered vacant by the resignation of the Rev. A. H. Cooke, whose labours on the Macandrew Collection in that Museum have been so highly appreciated by conchologists.

SIR WILLIAM GULL, F.R.S., was so distinguished a physician, and his name was so well known, that the tidings of his death excited a widespread feeling of regret. He died on Wednesday, January 29, from paralysis, and the funeral took place on Monday at the churchyard of Thorpe-le-Soken, Essex. He was in his seventy-fifth year.

WE regret to hear of the death of Dr. L. Taczanowski, which took place at Warsaw on January 11. He is best known for his standard work "Ornithologie du Pérou," but his contributions to the ornithology of Poland, of Siberia, and the Corea have also been numerous and important.

GERMAN papers announce the death of Otto Rosenberger, the well-known astronomer. He was born in Courland in 1810, and in 1831 was appointed to the charge of the Observatory at Halle, and at the same time was made Professor of Mathematics. This position he held during the rest of his long life. Rosenberger's name is known chiefly in association with his work relating to Halley's comet.

ANOTHER death which we are sorry to have to record is that of Prof. Neumayr, the geologist, of Vienna. He was only a little over forty years of age, and his death is a great loss.

ON February 15, Lord Rayleigh will begin a course of seven lectures at the Royal Institution. The subject will be electricity and magnetism.

THE Council of the Society of Arts have arranged that a course of lectures on "The Atmosphere" shall be given by Prof. V. Lewes on the following Saturday afternoons: March 8, 15, 22, and 29, at 3 o'clock.

MR. B. A. GOULD, Cambridge, Mass., has been appointed President of the American Metrological Society for the present year. Among the members of the Council of this Society are Messrs. Cleveland Abbe, H. A. Newton, Simon Newcomb, and S. P. Langley. The Society was founded in 1873, and its objects are to improve existing systems of weights, measures, and moneys, and to bring them into relations of simple commensurability with each other; to secure the universal adoption of common units of measure for quantities in physical observation or investigation, for which ordinary systems of metrology do not provide; to secure uniform usage as to standard points of reference, or physical conditions to which observations must be reduced for purposes of comparison; and to secure the use of the decimal system for denominations of weight, measure, and money derived from unit-bases, not necessarily excluding for practical purposes binary or other convenient divisions.

THE Committee of the Cambridge University Antiquarian Society in their fifth Annual Report state that, since the opening of the Archæological Museum in 1884, over 2800 objects and 900 books have been added to the collection. The most important additions have been made in the ethnological department, including (during the past year) General Scratchley's collections from New Guinea, a series of 500 specimens of implements and ornaments from the West Indies, presented by Colonel Fielden, who has also given many rare stone implements and weapons collected in South Africa, and a series of 70 specimens of dresses, weapons, &c., from the Solomon and Banks Islands and from Santa Cruz, presented by Bishop Selwyn. The Curator, Baron von Hügel, reports that during the long vacation he excavated with success a Roman refuse-pit and a burial-place at the eastern side of Alderney. The digging is to be resumed.

THE seventh annual dinner of the Association of Public Sanitary Inspectors was held on Saturday evening at the First Avenue Hotel, Holborn. Dr. B. W. Richardson presided, and proposed the toast of "The Association and its President, Sir Edwin Chadwick." The duties of the Association, he said, were to teach and protect its members, and all sanitary inspectors ought to belong to it. He hoped that the apathy at present shown by too many of them would not last any longer.

DR. A. N. BERLESE, of Padua, has been appointed Professor of Botany to the Royal Lyceum at Ascoli-Piceno; and Dr. J. H. Wakker, of Utrecht, Professor of Botany at the dairy school at Oudshoorn, Holland.

THE *Botanical Gazette* published at Crawfordsville, Indiana, gives some particulars of one of the most magnificent bequests ever made for scientific purposes, that of the late Mr. H. Shaw for the endowment of the Botanic Garden and School of Botany at St. Louis, Missouri, amounting to not less than between three and five million dollars. The trustees have determined to apply the income to the maintenance and increase in the scientific usefulness of the Botanic Garden; to provide fire-proof quarters for the invaluable herbarium of the late Dr. George Engelmann, and to supply means for its enlargement; to secure a botanical museum; and to gradually acquire and utilize facilities for research in vegetable physiology and histology, the diseases and injuries of plants, and other branches of botany and horticulture. To aid in the carrying out of this last purpose, travelling botanical scholarships have been established. The present very able director of the Botanic Garden is Dr. William Trelease.

The *Kew Bulletin* for February begins with some extracts from the Annual Report on the Government cinchona plantation and factory in Bengal for the year 1888–89. The valuable information presented in these extracts is given for the benefit of persons growing cinchona in countries which the documents for the Government of Bengal are little likely to reach. The new number also deals with the use of maqui berries for the colouring of wine, vine-culture in Tunis, phylloxera in Victoria, the botanical exploration of Cuba, and the sugar production of the world. The section on the last of these subjects relates to statistics brought together in Dr. Robert Giffen's report on the progress of the sugar trade. Commenting on the figures supplied in this report, the writer in the *Bulletin* says that if they "do not justify a gloomy view of the present position of the cane-sugar industry in British colonies, they scarcely justify a very optimistic one. It is obvious that the capital which should be applied to the improvement of manufacturing processes and machinery is, under present circumstances, practically diverted to the mere maintenance of the cultivation. And this in the long run must be a losing game. At present the fact stands that West Indian sugar has to a large extent been driven from the home market to that of the United States. If in time it should lose that, its fate apparently is sealed."

At the last meeting of the Paris Biological Society, Prof. Raphael Blanchard gave an interesting account of a peculiar pigment, hitherto found in plants only, *carotine*, which he has discovered in a crustacean in one of the Alpine lakes, near Briançon. Its functions are not yet known, but M. Blanchard intends to pursue his study of the subject on the spot. The animals cannot be transported alive to lower levels.

We are glad to welcome the first number of *The University Extension Journal*. The Society by which it is issued has become important enough to need an organ of its own; and the new periodical, which will appear at the beginning of every month, ought to be of service to all who are in any way interested in the movement.

The *Engineer* of January 31 contains a leading article on "Colour-blind Engine-drivers," and it is interesting to note what the leading technical journal has to say on the subject: "We do not say that no accident was ever brought about by the inability of a driver to distinguish between a green light and a red one, but we can say that nothing of such an accident is to be met with in the Board of Trade Reports." Our contemporary is of opinion that the testing of the sight of locomotive men should be made under working conditions, *i.e.* with actual signal lights.

A paper on mortality from snake-bite in the district of Ratnagherry was read lately before the Bombay Natural History Society by Mr. Vidal, of the Bombay Civil Service. Many of the deaths in that district are, he says, due to a small and insignificant-looking snake, called "foorsa" by the natives. It is a viper rarely more than a foot long, and is so sluggish that it does not move out of the way till trodden on. Thus it is much more dangerous than the stronger and fiercer cobra.

During the year 1889 no fewer than 28 bears, 115 wolves, and 45 wolf-cubs were shot in the single district of Travnik, in Bosnia.

Das Wetter for January contains:—(*a*) An article by Dr. R. Assmann on climatological considerations about the prevalent epidemic of influenza. From an experience of many years in dealing with the connection between climatic conditions and the state of health, the author gives the following conditions as the most favourable for spreading organisms in the air: (1) dryness of the soil, (2) deficiency of snow covering, (3) deficiency of rainfall, (4) existence of fog or low-hanging clouds, (5) prevalence of high barometer with a small intermingling of air in the vertical direction; and he shows that these conditions were prevalent in Eastern and Central Europe from the beginning of November; that atmospheric dust existed in great quantities, and was propagated westward by easterly, north-easterly, and south-easterly winds. He considers that changes of temperature had no important relation to the spread of the epidemic. (*b*) A lecture recently delivered to the Scientific Club in Vienna, on the general circulation of the atmosphere, by Dr. J. M. Pernter. He refers to the idea of the conflict of polar and equatorial winds so long supported by Dove and others, and shows that the publication of synoptic charts since the year 1863 has demonstrated that the above theory does not hold good for temperate and northern latitudes; that the circulation there depends upon the positions of the areas of high and low pressures, producing cyclones and anticyclones. Many dark points require explanation, such as the tracks which the cyclones follow, but much new light has recently been thrown upon the subject, especially by the researches of Ferrel, Oberbeck, and Abercromby.

Dr. Albrecht Penck, Professor of Physical Geography at the University of Vienna, lately called attention to the fact that no two official accounts of the area of the Austro-Hungarian monarchy agree. The difference between the highest and the lowest estimates amounts to 3313·75 square kilometres. By an examination of the new special map constructed by the Army Geographical Institute, which is on the scale of 1 to 75,000, and occupies 400 sheets, Prof. Penck has satisfied himself that the actual area of the Empire is 3247·12 square kilometres greater than is given in the latest published official account. The error arose chiefly from an incorrect triangulation of the Hungarian portion of the Empire, which is 3054·02 square kilometres larger than has been supposed.

It has hitherto been generally believed that the Montgolfier or hot-air balloon cannot be used in tropical climates. If this were true, ballooning for war purposes would of course be impossible in places where coal-gas could not be obtained. We learn from the *Times* that Mr. Percival Spencer, who has been making a series of interesting balloon experiments in Central India, has succeeded in showing that the theory is without foundation. At Secunderabad, in presence of the garrison and a crowd of European and native spectators, he lately made an ascent in his patent asbestos balloon. The inflation was effected by the burning of methylated spirit inside the balloon, which was held in place by 25 soldiers of the Bedford regiment until the word to "let go" was given. After rising to a considerable height, the aëronaut descended by means of his parachute. The spot where the ascent was made is over 2000 feet above the level of the sea, and the achievement was all the more remarkable because of the sultry climate and the great rarity of the air.

An interesting paper on "Some Terraced Hill Slopes of the Midlands," by Mr. Edwin A. Walford, has been reprinted from the Journal of the Northamptonshire Natural History Society. The factors in the formation of these terraced slopes Mr. Walford groups as follows:—(1) The slipping and sliding outwards of the saturated porous marls upon the tenacious clays at the line of drainage, aided doubtless by the pressure of the superincumbent rock bed. (2) Displacements caused by the removal by chemical and mechanical solution of certain constituents of the marls and marlstone by the passage of the surface water through them. (3) The sliding downwards of the surface soil, as described by Dr. Darwin, and latterly illustrated by Mr. A. Ernst. The suggestions offered by Mr. Walford agree in the main, as he himself points out, with those adopted by Mr. A. Ernst in his paper in Nature, February 28, 1889.

MESSRS. GAUTHIER-VILLARS (Paris) have recently added three new works to their already large list of photographic treatises. One is the "Manuel de Phototypie," by M. Bonnet, giving full details of the various processes for the rapid reproduction of photographs, such as is now demanded for many purposes. The formulæ are stated very clearly, and the apparatus required is sufficiently illustrated by diagrams. The treatise is thoroughly practical, and will be very valuable to all interested in the subject, whether as amateurs or for trade purposes. The second—"Temps de Pose"—is by M. Pluvinel, and deals with the difficult question of the time of exposure. It is shown that what is generally regarded as a rule-of-thumb process can be reduced to a scientific one. The various functions of the duration of the exposure are first considered mathematically, and it is then shown how the results of the investigations are to be applied practically, the method being illustrated by worked-out examples. To simplify matters, tables are given showing the different elements, such as coefficient of brightness, for all ordinary photographic subjects. The treatise is chiefly interesting as a scientific contribution, as few photographers will care to take the trouble of working out the time of exposure, now that they have found that good work can be done by judgment alone. The third book is in two volumes, and treats of the various "film" processes ("Procédés Pelliculaires," by George Balagny). It claims to give a full account of all that has been said and done in connection with the subject since the introduction of photography, and as far as we can judge, this claim is fully justified. Every detail of the subject is considered in a very practical manner. One of the most interesting applications of flexible films mentioned is the registration of flash signals in "optical telegraphy."

THE "Year-book of Photography" (Piper and Castle) for 1890 fully bears out the good reputation gained by its predecessors. In addition to the information relating to the various photographic societies, there are several articles on the advances in photographic processes which have been made during the past year, and other useful notes. One of the most interesting articles is that by the editor on photography in natural colours, from which we learn that "processes of practical value, to achieve the end, are likely to be discovered by the exercise of ability and perseverance." The only important omission we notice is a record of the remarkable achievements in astronomical photography. The volume contains a portrait and short biographical notice of Edmond Becquerel. The whole forms an invaluable book of reference to all photographic matters, with the exception referred to.

MESSRS. GEORGE BELL AND SONS have published "The School Calendar and Hand-book of Examinations, Scholarships, and Exhibitions, 1890." This is the fourth year of issue, and great pains have been taken, as in former years, to secure that the information brought together shall be full and trustworthy. A preface is contributed by Mr. F. Storr.

THE sixteenth part of Cassell's "New Popular Educator" has been issued. It includes a map of Australasia.

THE Proceedings of the International Zoological Congress, held in Paris last summer, will be ready for distribution in a fortnight.

A NEW and very simple method of synthesizing indigo has been discovered by Dr. Flimm, of Darmstadt (*Ber. deut. chem. Ges.*, No. 1, 1890, p. 57). In studying the action of caustic alkalies upon the monobromine derivative of acetanilide, $C_6H_5.NH.CO.CH_2Br$, a solid melting at 131°·5, it was found that when this substance was fused with caustic potash a product was obtained which at once gave an indigo blue colour on the addition of water, and quite a considerable quantity of a blue solid resembling indigo separated out. The best mode of carrying out the operation is described by Dr. Flimm as follows:—The monobromacetanilide is carefully mixed with dry caustic potash in a mortar, and the mixture introduced into a retort and heated rapidly until a homogeneous reddish-brown melt is obtained This is subsequently dissolved in water, and a little ammonia or ammonium chloride solution added, when the liquid immediately becomes coloured green, which colour rapidly changes into a dark blue, and in a short time the blue colouring matter is for the most part deposited upon the bottom of the vessel in which the operation is performed. The fused mass may also conveniently be dissolved in dilute hydrochloric acid, and a little ferric chloride added, when the formation of indigo takes place immediately. The collected blue colouring matter may be readily obtained pure by washing first with dilute hydrochloric acid and afterwards with alcohol. That this blue substance was really common indigo was proved by the fact that it yielded several of the most characteristic reactions of indigotin, such as solubility in aniline, paraffin, and chloroform, its sublimation, and the formation of sulphonic acids, which gave similar changes of colour with nitric acid to those of indigotin. The final proof was afforded by its reduction to indigo white and re-oxidation to indigo blue by exposure to air. Moreover, the absorption spectrum of the colouring matter was found to be identical with the well-known absorption spectrum of indigo. Hence there can be no doubt that indigo is really formed by this very simple process. The chemical changes occurring in the reaction are considered by Dr. Flimm to be the following:—Indigo blue is not produced directly, but first, as a condensation product of the monobromacetanilide, indoxyl is formed, $C_6H_4\left<\begin{matrix}NH\\COH\end{matrix}\right>CH$, or more probably a pseudo-indoxyl of the isomeric constitution $C_6H_4\left<\begin{matrix}NH\\CO\end{matrix}\right>CH_2$. This intermediate substance then passes over by oxidation into indigo, $C_6H_4\left<\begin{matrix}NH\\CO\end{matrix}\right>C{=}C\left<\begin{matrix}NH\\CO\end{matrix}\right>C_6H_4$, two molecules each losing two atoms of hydrogen by oxidation, and then condensing to form indigo. It was not found possible to isolate the intermediate pseudo-indoxyl, owing to its extreme instability; indeed, the all-important point to be observed in the practical carrying out of the synthesis by this method is that the fusion must be performed quickly and the temperature raised rapidly to a considerable height, the whole process occupying only a few minutes. The yield of pure indigo under the conditions yet investigated is not very large, amounting to about four per cent. of the weight of the original anilide.

THE additions to the Zoological Society's Gardens during the past week include thirteen Cuning's Octodons (*Octodon cuningi*) from Chili, presented by Mr. W. H. Newman; five Common Dormice (*Muscardinus avellanarius*), British, presented by Mr. Florance Wyndham; a Large Hill-Mynah (*Gracula intermedia*) from India, deposited; a Dingo (*Canis dingo*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Remarks.

(1) The spectrum of this nebula has not yet, so far as I know, been recorded, but the observation will not be difficult, if one may judge from the description given by Herschel, namely: "Very bright, pretty large, round, much brighter in the middle, mottled as if with stars."

(2) This star has a spectrum of the Group II. type, Dunér describing it as very beautiful. He states that all the bands, 1-9, are very wide and dark. The observations most likely to extend our knowledge of the group of bodies to which this star belongs are (1) observations of the bright carbon flutings (see p. 305); (2) comparisons with the flame spectra of manganese, magnesium, and lead; (3) observations made with special reference to the presence or absence of absorption lines, of which Dunér makes no mention.

(3) Gothard classes this with stars of the solar type. The usual differential observations are required.

(4) A star of Group IV. The usual observations of the relative intensities of the hydrogen and metallic lines (*b*, D, &c.), as compared with other stars, are required.

(5) A rather faint star of Group VI., in which the character of band 6 (near λ 564), as compared with the other carbon bands (9 and 10), requires further attention. Secondary bands should also be looked for.

(6) This variable is stated by Gore to have a continuous spectrum, but it seems probable that lines or flutings will be found if the star be examined under the most favourable conditions—that is, when near maximum. Rigel was formerly said to have a "continuous" spectrum, but the lines are now by no means difficult to see. The star ranges from magnitude 6 at maximum to 7·2 at minimum, and the period is 31–50 days (Gore). A. FOWLER.

TOTAL SOLAR ECLIPSE OF 1886.—Dr. Schuster has thus summarized the spectroscopic results he obtained at this eclipse (Phil. Trans., vol. 180, 1889):—

(1) The continuous spectrum of the corona has the maximum of actinic intensity displaced considerably towards the red, when compared with the spectrum of sunlight.

(2) While, on the two previous occasions on which photographs of the spectrum were obtained, lines showed themselves outside the limits of the corona, this was not the case in 1886.

(3) Calcium and hydrogen do not form part of the normal spectrum of the corona. The hydrogen lines are visible only in the parts overlying strong prominences; the H and K lines of calcium, though visible everywhere, are stronger on that side of the corona which has many prominences at its base.

(4) The strongest corona line in 1886 was at $\lambda = 4232·8$; this is probably the 4233·0 line often observed by Young in the chromosphere.

(5) Of the other strong lines, the positions of the following seem pretty well established:—

4056·7 **4084·2** 4089·3 **4169·7** **4195·0** **4211·8**
4280·6 4365·4 **4372·2** 4378·1 4485·6 4627·9

The lines printed in thicker type have been observed also at the Caroline Island and Egyptian Eclipses.

(6) A comparison between the lines of the corona and the lines of terrestrial elements has led to negative results.

ANNUAIRE DU BUREAU DES LONGITUDES.—In the volume for 1890, MM. Lœwy and Schulhof contribute a list of the comets which appeared from 1825 to 1835 inclusive, and in 1888, being a continuation of the lists given in former years. M. Lœwy also gives a complete table of the appearances of the planets throughout 1890, and ephemerides of a considerable number of variable stars. An elaborate comparison of the various calendars is from the pen of M. Cornu, and under the head of the solar system a rich store of information is included. With the notices we find an account of the meeting of the permanent committee of the photographic chart of the heavens and the Photographic Congress of September last. This year's *Annuaire* is as completely filled with information as it has ever been and doubtless will be as much appreciated by astronomers.

ANNUAIRE DE L'OBSERVATOIRE ROYAL DE BRUXELLES.—The volume for 1890 is the fifty-seventh annual publication from this Observatory. It contains tables of the mean positions of the principal stars and their apparent right ascensions, of the occultation of stars by the moon, and of eclipses of Jupiter's satellites, mention being also made of remarkable phenomena relating to the moon and the planets. M. Folie gives a biographical sketch of his predecessor, J. C. Houzeau, which is embellished with the portrait of this deceased bibliographer. Considerable attention has been paid to the researches on diurnal nutation and the determination of the constant. M. Spee discusses the tabulated observations of the condition of the sun's surface during 1888, and M. Moreau contributes an interesting note on the movement of a solid about a fixed point. A list is also given of the comets and asteroids discovered in 1889, and some of the particulars relating to their orbits.

ROYAL ASTRONOMICAL SOCIETY.—The annual general meeting of the Fellows of this Society will be held at Burlington House on Friday, the 14th inst., for the purpose of receiving the Report of the Council, electing officers for the ensuing year, and transacting other business of the Society. The chair will be taken at 3 o'clock precisely.

Erratum.—In the elements of companion C of Brook's comet (p. 305), read ☊ = 17° 52′ 24″·5, and log *a* = 0 565059.

GEOGRAPHICAL NOTES.

BARON NORDENSKIÖLD has announced in the Swedish Academy of Sciences, that he and Baron Oscar Dickson, with assistance from the Australian colonies, will start on an expedition in the South Polar regions next year.

A RECENT telegram from Tashkent announced that Colonel Pevtsoff and M. Roborovsky had discovered a convenient pass to the north-western part of Tibet, from Nia, and had mounted to the great table-land. The plateau has there an altitude of 12,000 feet above the sea, and the country round is desolate and uninhabited, while towards the south the plateau is well watered and wooded. The Tashkent telegram is so expressed that it might be supposed to mean that two separate passes had been discovered by the two explorers. But the news received from the expedition at St. Petersburg on December 26, and dated October 27, shows that both explorers proposed to leave the oasis of Keria (100 miles to the east of Khotan) on the next day, for Nia (65 miles further east) and there to search for a passage across the border-ridge which received from Prjevalsky the name of the "Russian ridge." This immense snow-clad chain separates the deserts of Eastern Turkestan from the trapezoidal space, the interior of which is quite unknown yet, and which is bordered by the "Russian" ridge and the Altyn-tagh in the north-west; the ridges of Tsaidam and those named by Prjevalsky "Columbus" and "Marco-Polo" in the north-east; the highlands (explored by Prjevalsky in 1879–80) at the sources of the Blue River, in the south-east; and a long, yet unnamed ridge which seems to be a prolongation of the Tan-la, in the south-west. The pass leading to that plateau from Nia, and now discovered by the Russian expedition, is situated some 80 miles to the east of the well-known pass across the Kuen-lun Mountains which leads from Southern Khotan to Lake Yashi-kul. M. Roborovsky's intention is evidently next to move up the Tchertchen river and to endeavour to reach the ridges "Moscow" and "Lake Unfreezing" (11,700 feet high), which were visited by Prjevalsky from the east during his last journey. Having succeeded in finding a pass to Tibet in the south of Nia, Colonel Pevtsoff proposes, as soon as the spring comes, to proceed himself by this pass to the table-land, while M. Roborovsky probably will be despatched to explore the same border-ridge further east, in the south of Tchertchen.

THE *Boletin* of the Madrid Geographical Society for the last quarter of 1889 contains a most valuable memoir by Dr. Fernando Blumentritt, on the intricate ethnology of the Philippine Islands. The author classifies the whole of the native population in three broad divisions—Negrito, Malay, and Mongoloid; the last comprising those tribes which in their physical appearance betray certain Chinese or Japanese affinities. All are grouped in an admirably arranged alphabetical table, where their names, race, language, religion, culture, locality, and numbers are briefly specified in seven parallel columns. With a few variants and cross-references this table contains no less than 159 entries, and thus conveys in summary form all the essential particulars regarding every known tribe in the Philippine Archipelago. From it we gather that the Negritoes—that is, the true autochthonous element, variously known as Aetas, Attas, Atés, Etas, Itas, Mamánuas, &c., and physically belonging to the same stock as the Samangs of the Malay Peninsula—

are now reduced to about 20,000, dispersed in small groups over the islands of Luzon, Mindoro, Tablas, Panay, Negros, Cebu, Paragan (Palawan), and Mindanao. A few also appear still to survive in Alabat, Busuanga, and Culioú. Of the Malay peoples by far the most numerous and important are the southern Bisayas (Visayas), and the northern Tagalas, both described as "civilized Christians," and numbering respectively 1,700,000 and 1,250,000. These two peoples are steadily encroaching on all the surrounding tribes, causing them to disappear by a gradual process of absorption or assimilation, and the time is approaching when the whole of the islands will be divided into two great nationalities bearing somewhat the same relation to each other that the High German does to the Low German branch of the Teutonic family.

SMOKELESS EXPLOSIVES.[1]

I.

THE production of smoke which attends the ignition or explosion of gunpowder is often a source of considerable inconvenience in connection with its application to naval or military purposes, its employment in mines, and its use by the sportsman, although occasions not unfrequently arise during naval and military operations when the shroud of smoke produced by musketry or artillery fire has proved of important advantage to one or other, or to both, of the belligerents during different periods of an engagement.

Until within the last few years, however, but little, if any, thought appears to have been given to the possibility of dispensing with or greatly diminishing the production of smoke in the application of fire-arms, excepting in connection with sport. The inconvenience and disappointment often resulting from the obscuring effects of a neighbouring gun-discharge, or of the first shot from a double-barrel arm, led the sportsman to look hopefully to gun-cotton, directly after its first production in 1846, as a probable source of greater comfort and brighter prospects in the pursuit of his pastime and in his strivings for success.

A comparison between the chemical changes attending the burning, explosion, or metamorphosis of gun-cotton and of gunpowder, serves to explain the cause of the production of smoke in the latter case, and the reason of smokelessness in the case of gun-cotton. Whilst the products of explosion of the latter consist exclusively of gases, and of water which assumes the transparent form of highly-heated vapour at the moment of its production, the explosive substances classed as gunpowder, and which consist of mixtures of saltpetre, or another nitrate of a metal, with charred wood or other carbonized vegetable matter, and with variable quantities of sulphur, furnish products, of which very large proportions are not gaseous, even at high temperatures. Upon the ignition of such a mixture, these products are in part deposited in the form of a fused residue, which constitutes the fouling in a fire-arm, and are in part distributed, in an extremely fine state of division, through the gases and vapours developed by the explosion, thus producing smoke.

In the case of gunpowder of ordinary composition, the solid products amount to over fifty per cent. by weight of the total products of explosion, and the dense white smoke which it produces consists partly of extremely finely-divided potassium carbonate, which is a component of the solid products, and, to a great extent, of potassium sulphate produced chiefly by the burning of one of the important solid products of explosion—potassium sulphide—when it is carried in a fine state of division into the air by the rush of gas.

With other explosives, which are also smoke-producing, the formation of the smoke is due to the fact that one or other of the products, although existing as vapour at the instant of its development, is immediately condensed to a cloud composed of minute liquid particles, or of vesicles, as in the case of mercury vapour liberated upon the explosion of mercuric fulminate, or of the aqueous vapour produced upon the ignition of a mixture of ammonium nitrate and charcoal, or ammonium nitrate and picric acid.

Until within the last half-dozen years, the varieties of gunpowder which have been applied to war purposes in this and other countries have exhibited comparatively few variations in chemical composition. The proportions of charcoal, saltpetre, and sulphur employed in their production exhibit slight differences in different countries, and these, as well as the character of the charcoal used, its sources and method of production, underwent but little modification for very many years. The same remark applies to the nature of the successive operations pursued in the manufacture of black powder for artillery purposes in this and other countries.

The replacement of smooth-bore guns by rifled artillery which followed the Crimean war, and the increase in the size and power of guns consequent upon the application of armour to ships and forts, soon called for the pursuit of investigations having for their object the attainment of means for variously modifying the action of fired gunpowder, so as to render it suitable for the different calibres of guns, whose full power could not be effectively, or in some instances safely, developed by the use of the kind of gunpowder previously employed indiscriminately in artillery of all known calibres.

In order to control the violence of explosion of gunpowder, by modifying the rapidity of transmission of explosion from particle to particle, or through the mass of each individual particle, of which the charge of a gun is composed, the accomplishment of the desired results was, in the first instance, and indeed throughout practical investigations extending over many years, sought exclusively in modifications of the size and form of the individual masses composing a charge of powder, and of their density and hardness, it being considered that, as the proportions of saltpetre, charcoal, and sulphur generally employed in the production of gunpowder very nearly correspond to those required for the development of the greatest chemical energy by those incorporated materials, it was advisable to seek for the attainment of the desired results by modifications of the physical and mechanical characters of, rather than by any modification in the proportions and chemical characters of, its ingredients.

The varieties of powder, which, as the outcome of careful practical and scientific researches in this direction, have been introduced into artillery service from time to time, and some of which, at any rate, have proved fairly efficient, have been of two distinct types. The first of these, produced by breaking up more or less highly-pressed cakes of black powder into grains, pebbles, or boulders, of approximately uniform size and shape, the sharp edges and rough surfaces being afterwards removed by attrition (reeling and glazing), are simply a further development of one of the original forms of granulated or corned powder, represented by the old F. G., or small arms, and L. G., or cannon powder. Gunpowder of this class, ranging in size from about 1000 pieces to the ounce, to about six pieces to the pound, have been introduced into artillery service, and certain of them, viz. R. L. G. (rifle large grain), which was the first step in advance upon the old cannon-powder (L. G.); pebble-powder (P.), and large pebble or boulder-powder (P. 2), are still employed more or less extensively in some guns of the present day.

The other type of powder has no representative among the more ancient varieties; it has its origin in the obviously sound theoretical view that uniformity in the results furnished by a particular powder, when employed under like conditions, demands not merely identity in regard to composition, but also identity in form, size, density, and structure of the individual masses composing the charge used in a gun. The practical realization of this view should obviously be attained, or at any rate approached, by submitting equal quantities of one and the same mixture of ingredients, presented in the form of powder of uniform fineness and dryness, to a uniform pressure for a fixed period in moulds of uniform size, and under surrounding conditions as nearly as possible alike. The fulfilment of these conditions would, moreover, have to be supplemented by an equally uniform course of proceeding in the subsequent drying and other finishing processes to which the powder-masses would be submitted.

The only form of powder, introduced into our artillery service for a brief period, in the production of which these conditions were adhered to as closely as possible, was a so-called pellet powder, which consisted of small cylinders having semi-perforations with the object of increasing the total inflaming surface of the individual masses.

Practical experience with this powder, and with others prepared upon the same system, but with much less rigorous regard to uniformity in such details as state of division and condition of dryness of the powder before its compression into cylindrical or other forms, showed that uniformity in the ballistic properties

[1] Friday Evening Discourse delivered by Sir Frederick Abel, F.R.S., at the Royal Institution of Great Britain, on January 31, 1890.

of black powder could be as well and even more readily secured by the thorough blending or mixing together of batches presenting some variation in regard to density, hardness, or other features, as by aiming at an approach to absolute uniformity in the characters of each individual mass composing a charge.

At the time that our attention was first actively given to this subject of the modification of the ballistic properties of powder, it had already been to some extent dealt with in the United States by Rodman and Doremus, and the latter was the first to propose the application, as charges for guns, of powder-masses produced by the compression of coarsely grained powder into moulds of prismatic form. In Russia the first step was taken to utilize the results arrived at by Doremus, and to adopt a prismatic powder for use in guns of large calibre.

Side by side with the development and perfection of the manufacture of prismatic powder in Russia, Germany, and in this country, new experiments on the production of powder-masses suitable, by their comparatively gradual action, for employment in the very large charges required for the heavy artillery of the present day, by the powerful compression of mixtures of more or less finely broken up powder-cake into masses of greater size than those of the pebble, pellet, and prism powders, were actively pursued in Italy, and also by our own Government Committee on Explosives, and the outcome of very exhaustive practical investigations were the very efficient Fossano powder, or *poudre progressif*, of the Italians, and the boulder and large cylindrical powders known as P^2 and C^2, produced at Waltham Abbey, which scarcely vied, however, with the Italian powder in the uniformity of their ballistic properties.

Researches carried out by Captain Noble and the lecturer some years ago with a series of gunpowders differing considerably in composition from each other, indicated that advantages might be secured in the production of powders for heavy guns by so modifying the proportions of the constituents (*e.g.* by considerably increasing the proportion of charcoal and reducing the proportion of sulphur) as to give rise to the production of a much greater volume of gas, and at the same time to diminish the heat developed by the explosion.

These researches served, among other purposes, to throw considerable light upon the cause of the wearing or erosive action of powder-explosions upon the inner surface of the gun, which in time may produce so serious a deterioration of the arm as to diminish the velocity of projection considerably, and so affect the accuracy of shooting, a deterioration which increases in extent in an increasing ratio to the size of the guns, in consequence, obviously, of the large increase in the weight of the charges fired.

Several causes undoubtedly combine to bring about the wearing away of the gun's bore, which is especially great where the products of explosion, while under the maximum pressure, can escape between the projectile and the bore of the gun. The great velocity with which the very highly heated gaseous and liquid (fused solid) products of explosion sweep over the heated surface of the metal gives rise to a displacement of the particles composing it, which increases as the surface becomes roughened by the first action upon the least compact portions of the metal, and thus opposes greater resistance; at the same time, the effect of the high temperature to which the surface is raised is to reduce its rigidity and power of resisting the force of the gaseous torrent, and lastly some amount of chemical action upon the metal, by certain of the highly heated non-gaseous products of explosion, contributes towards an increase in the erosive effects. A series of careful experiments made by Captain Noble with powders of different composition, and with other explosives, afforded decisive evidence that the material which furnished the largest proportion of gaseous products, and the explosion of which was attended by the development of the smallest amount of heat, exerted least erosive action.

It is probable that important changes in the composition of powders manufactured by us for our heavy guns would have resulted from those researches, but in the meantime, two eminent German gunpowder manufacturers had occupied themselves independently, and simultaneously, with the important practical question of producing some more suitable powder for heavy guns than the various new forms of ordinary black powder, the rate of burning of which, especially when confined in a close chamber, was, after all, reduced only in a moderate degree by the increase in the size of the masses, and by such increase in their density as it was practicable to attain. The German experimenters directed their attention not merely to the proportions in which the powder ingredients are employed, but also to a modification in the character of charcoal, and the success attending their labours in these directions led to the practically simultaneous production, by Mr. Heidemann at the Westphalia Powder Works, and Mr. Düttenhofer at the Rottweil Works near Hamburg, of a prismatic powder of cocoa-brown colour, consisting of saltpetre in somewhat higher proportion, of sulphur in much lower proportion, than in normal black powder, and of very slightly burned charcoal, similar in composition to the charcoal (*charbon roux*) which Violette, a French chemist, first produced in 1847 by the action of superheated steam upon wood or other vegetable matter, and which he proposed for employment in the manufacture of sporting powder. These brown prismatic powders (or "cocoa-powders," as they were termed from their colour), are distinguished from black powder not only by their appearance, but also by their very slow combustion in open air, by their comparatively gradual and long-sustained action when used in guns, and by the simple character of their products of explosion as compared with those of black powder. As the oxidizing ingredient, saltpetre, is contained, in brown or cocoa powder, in larger proportion relatively to the oxidizable components, sulphur and charcoal, than in black powder, these become fully oxidized, while the products of explosion of the latter contain, on the other hand, larger proportions of unoxidized material, or only partially oxidized products. Moreover, there is produced upon the explosion of brown powder a relatively very large amount of water-vapour, not merely because the finished powder contains a larger proportion of water than black powder, but also because the very slightly charred wood or straw used in the brown powder is much richer in hydrogen than black charcoal, and therefore furnishes by its oxidation a considerable amount of water. The total volume of gas furnished by the brown powder (at 0° C. and 760 mm. barometer) is only about 200 volumes per kilogramme of powder, against 278 volumes furnished by a normal sample of black powder, but the amount of water-vapour furnished upon its explosion is about three times that produced from black powder, and this would make the volume of gas and vapour developed by the two powders about equal if the heat of its explosion were the same in the two cases; the actual temperature produced by the explosion of brown powder, is, however, somewhat the higher of the two.

Although the smoke produced upon firing a charge of brown powder from a gun appears at first but little different in denseness to that of black powder, it certainly disperses much more rapidly, a difference which is probably due to the speedy absorption, by solution, of the finely divided potassium salts by the large proportion of water-vapour distributed throughout the so-called smoke.

This class of powder was substituted with considerable advantage for black powder in guns of comparatively large calibre; nevertheless it became desirable to attain even slower or more gradual action in the case of the very large charges required for guns of the heaviest calibres, such as those which propel shot of about 2000 pounds weight. Accordingly, the brown powder has been modified in regard to the proportions of its ingredients to suit these conditions, while, on the other hand, powder intermediate with respect to rapidity of action between black pebble powder and the brown powder, has been found more suitable than the former for use in guns of moderately large calibre.

The recent successful adaptation of machine guns and comparatively large quick-firing guns to naval service, more especially for the defence of ships against attack by torpedo boats, &c., has rendered the provision of a powder for use with them, which would produce comparatively little or no smoke, a matter of very considerable importance, inasmuch as the efficiency of such defence must be greatly diminished by the circumstance that, after a very brief use of the guns with black powder, the objects against which their fire is destined to operate, become more or less completely hidden from those directing them, by the dense veil of powder-smoke produced. Hence much attention has been directed during the last few years to the production of smokeless, or nearly smokeless powders for naval use in the above directions. At the same time, the views of many military authorities regarding the importance of dispensing with smoke in land engagements has also created a demand, the apparent urgency of which has been increased by various circumstances,

for a smokeless powder suitable for field artillery and small arms.

The properties of ammonium nitrate, of which the products of decomposition by heat are, in addition to water-vapour, entirely gaseous, have rendered it a tempting material to work upon in the hands of those who have striven to produce a smokeless powder, but its deliquescent character has been the chief obstacle to its application as a component of an explosive agent susceptible of substitution for black powder for service purposes.

A German chemical engineer, F. Gäus, conceived that, by incorporating charcoal and saltpetre with a particular proportion of ammonium nitrate, he had produced an explosive material which did not partake of the hygroscopic character common to other ammonium-nitrate mixtures, and that, by its explosion, the potassium in the saltpetre formed a volatile combination with nitrogen and hydrogen, a *potassium amide*, so that, although containing nearly half its weight of potassium salt, it would furnish only volatile products. The views of Mr. Gäus regarding the changes which his so-called *amide powder* undergoes upon explosion were not borne out by existing chemical knowledge, while the powder compounded in accordance with his views proved to be by no means smokeless, and was certainly not non-hygroscopic. Mr. Heidemann has, however, been successful, by modifications of Gäus's prescription and by application of his own special experience in powder-manufacture, in producing an ammonium-nitrate powder possessed of remarkable ballistic properties, furnishing comparatively little smoke, which speedily disperses, and exhibiting the hygroscopic characteristics of ammonium-nitrate preparations in a decidedly less degree than any other hitherto prepared. The powder, while yielding a very much larger volume of gas and water-vapour than black or brown powder, is considerably slower than the latter; the charge required to produce equal ballistic results is less, while the chamber-pressure developed is lower, and the pressures along the chase of the gun are higher, than in the case of brown powder.

The ammonium-nitrate powder contains, in its normal, dried condition, more water than even brown powder; it does not exhibit any great tendency to absorb moisture from an ordinarily dry or even a somewhat moist atmosphere, but if the amount of atmospheric moisture approaches saturation, it will rapidly absorb water, and when once the process begins it continues rapidly, the powder-masses becoming speedily quite pasty. The charges for quick-firing guns are enclosed in metal cases, in which they are securely sealed up; the powder is therefore prevented from absorbing moisture from the external air, but it has been found that if the cartridges are kept for long periods in ships' magazines, in which, from their position relatively to the ships' boilers, the temperature is more or less elevated, sometimes for considerable periods, the expulsion of water from some portions of the powder-masses composing the hermetically sealed charge, and its consequent irregular distribution, may give rise to want of uniformity in the action of the powder, and to the occasional development of high pressures. Although, therefore, this ammonium-nitrate powder may be regarded as the first successful advance towards the production of a comparatively smokeless artillery powder, it is not uniformly well adapted to the requirements which it should fulfil in naval service.

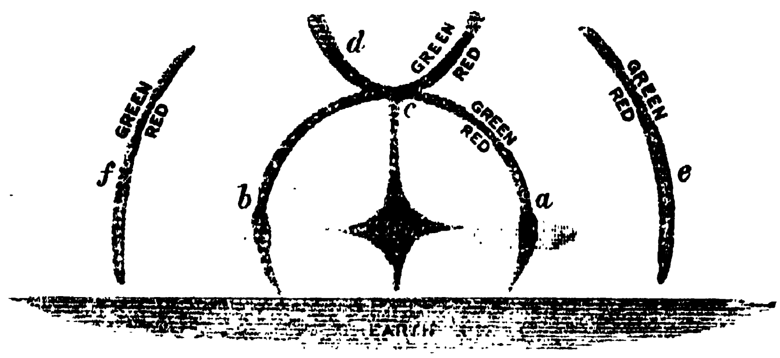
Attention was first seriously directed to the subject of smokeless powder by the reports received about four years ago of remarkable results stated to have been obtained in France with such a powder for use with the magazine rifle (the Lebel) which was being adapted to military service. These reports were speedily followed by others, descriptive of marvellous velocities obtained with small charges of this powder, or some modifications of it, from guns of very great length. As in the case of mélinite, the fabulously destructive effects of which were much vaunted at about the same time, the secret of the precise nature of the smokeless powder was so well preserved by the French authorities, that surmises could only be made on the subject even by those most conversant with these matters. It is now well known, however, that more than one smokeless explosive has succeeded the original powder, the perfection of which was reported to be beyond dispute, and that the material now adopted for use in the Lebel rifle bears, at any rate, great similarity to preparations which have been made the subject of patents in this country, and which are still experimental powders in other countries.

(*To be continued.*)

SOLAR HALOS AND PARHELIA.

THE recent appearance of solar and lunar halos, parhelia, and paraselene, has called forth a considerable amount of correspondence from all parts of the country, and the accompanying figure may be taken as a composite representation of the solar phenomenon observed. A glance at the times at which the halos were observed on the 29th ult., makes it apparent that they occurred earliest in places of highest latitudes. At Driffield, in lat. 54°, the halo, with its attendant parhelia, was observed at 1.34 p.m., and the whole phenomenon disappeared at 2.8 p.m.; at Burton-on-Trent, lat. 52° 48′, the halos and parhelia were first observed at 2 p.m., and lasted more or less distinctly until 3 p.m.; whilst about a degree south of this, at Oxford, Colnbrook, and Walton-on-Thames, the phenomena occurred from about 3.30 to 4.30. The uniform difference in the times when the halos were observed at the places of different latitudes necessarily follows from the fact that they are formed by the action upon solar rays of prismatic crystals of ice suspended in the air by the ascending currents which especially occur in the spring and autumn. Those prisms that are in such positions that the rays from the sun in transmission through them suffer minimum deviation are the cause of the formation of halos, and since the angular distance of the sun equal to minimum deviation is about 22°, this must be the radius of the halo, and the external circle, being produced by two such refractions in succession, has a radius of about 46°.

The halos recently observed do not differ in the main from those frequently seen in higher latitudes, and consisting of (1) a first circle or halo concentric with the sun, red within, violet without, and at an angular distance of 22° or 23°; (2) a second circle or halo, similar to the preceding, but at an angular distance of 46°; (3) a portion of the *parhelic* circle appearing horizontal and diametral, and at the points of junction of this circle with the two halos, there is increased luminosity, which have been taken for images of the sun; (4) horizontal arcs, tangents to the circular halos, and a vertical line making a cross with the horizontal portion of the parhelic circle.



a was seen at 3.35 p.m.; *b* at 3.45 p.m.; *c* and *d* at 3.50 p.m.; *e* at 4.0 p.m.; *f* at 4.10 p.m.

Mr. John Lovell thus describes the phenomena observed at Driffield:—"A splendid solar halo, with its attendant parhelia, was observed this afternoon at 1.34 local time. The halo (diameter 45°) was almost perfect, the lower part only being slightly obliterated by the thick atmosphere near the horizon. Attached to the upper side, an inverted portion of a similar halo appeared, brilliantly illumined on the concave side, the lower part giving out a dull red light. Again, 22½° above this, and also inverted, about 60° of arc beautifully coloured with rainbow colours was clearly visible, the red side lowest. This arc, if it had been produced, would have circled the zenith. The mock lights on each side of the halo were drawn out into long cones of intensely bright light, while the inner sky of the halo was of a very dark shade. The most noteworthy feature of the display was a brilliant patch of pure white light in the north-western sky, at a distance of 90° from the western mock sun, and undoubtedly emanating from it, and which remained visible for nearly ten minutes. The whole phenomena disappeared at 2.8 p.m., the sky then being covered with streaky cirro-stratus haze from the north-north-west."

The patch of white light referred to by Mr. Lovell was doubtless produced by the junction of the parhelic circle with one of the halos concentric with the sun. It is perhaps hardly necessary to note the relation that exists between halos and cirro-

stratus clouds, and that the space included within the halo is frequently of a more intense grey, or of a deeper blue than the rest of the sky.

The son of Sir W. Herschel observed the phenomena at Oxford, and noted:—"The sun was near the horizon. On either side of it, at a distance of five or six diameters of the sun, was a mock sun, not very bright, of the colours of the rainbow, the one on the right being the brighter. There was a scarcely perceptible rainbow, of which red was the only colour visible, joining the two mock suns. This rainbow was brightest directly over the sun. As far off again as the first was a second rainbow, hazy, but fairly bright, which was equally visible from earth to earth. Vertically above the sun, a third, a very bright rainbow, touched the second, being inverted, and having its centre straight overhead. It did not look quite as large as the second. The weather was clear, but the clouds on and above the horizon were of a uniform grey colour, fading off gradually to a nearly clear sky overhead. There seemed always to be a much lighter shade of grey in the clouds where the sun and the two mock suns were."

The coloured parhelia observed indicates the refraction and dispersion of solar light by vertical prisms, whilst the phenomena of inverted arches are produced by the light which passes through horizontal crystals, at different azimuths.

Mr. Frank E. Lott, at Burton-on-Trent, observed a third parhelia on the part of the first halo vertically above the sun, whilst Mr. H. G. Williams, of Caterham, observing the phenomena about 4 p.m., noted that the sun appeared about 10° above the horizon. So far, the observations of two or three parhelia with two halos and two inverted arches agree with many former descriptions. In the diagram appended, however, and in the majority of sketches received, the inverted arch is not given as the arc of a circle, but hyperbolic.

Mr. A. J. Butler, observing at Walton-on-Thames, remarks: "The hyperbolic band above the sun was carefully noted;" and Mr. C. A. Carus-Wilson, in the following observation made at Staines, supports this view:—

"The sun was just setting behind a bank of hazy mist, appearing as a crimson disk enveloped in blue grey cloud; I first noticed a distinct bow, of light grey tint, and coloured for a short distance at its left extremity with the ordinary rainbow tints—red inside. There then appeared a part of a second bow outside the other, coloured throughout the whole length visible—red inside. From the sun vertically upwards to the first bow, there was a band of white light, quite distinct from the light grey tint of the lower bow, and above the lower bow this band continued as a hyperbolic brush of white light: this brush was much brighter and better defined than the vertical band. A hasty measurement, with a pocket sextant, of the angular radii of the two bows, gave 46° and 23° for the outside and inside bows respectively."

Mr. H. W. Pyddoke also remarks:—"The most noticeable thing of all was the shape of the upper bow, which was like a hyberbole except at its ends where it bent round again very slightly;" and other correspondents concur in this description of the shape of the first inverted arch.

From the descriptions and figures given it is evident that the two parhelia on the parhelic circle are the respective centres of halos similar to the first halo concentric with the real sun; the intersection of these two circles with that surrounding the sun gives the appearance of a hyperbolic curve at the top of it. An exactly similar appearance was drawn by Pastorff as occurring on December 29, 1789, and is found in his "Beobachtungen der Sonnenflecke"; and *L'Astronomie* for August 1889 contains a drawing and description of a very similar appearance.

Lunar halos followed the solar halos on the 29th ult., and on the following day Mr. G. B. Buckton, F.R.S., observed three fine parhelia and a halo at Haslemere, and describes them as follows:—

"The sun shone brightly, but through a moderate haze. On the right and on the left, at equal altitudes with the sun, an oblong bright patch of light appeared. That on the left was the brightest, and formed a blurred image of the sun with all the prismatic colours of the rainbow, but the colours were reversed in order. The upper and lower parts of these mock suns were drawn out, and formed portions of a large circle of about (by eye estimate) 20° radius. These images were connected with the haze, but a lower stratum of finely striated cloud came between the eye and these patches. Immediately above the true sun a third patch of light occurred, through which a portion of an inverted circle was seen, the greater part of which was lost in the blue of the sky above. The right-hand mock sun was fainter than the other, on account of the grey haze being more dense."

Mr. Buckton's observation is a demonstration of the principle laid down—namely, that parhelia always appear at the same elevation as the true sun, and are united to each other by a white horizontal circle, whose pole is the zenith. This circle changes in elevation with the true sun; and the apparent semi-diameter is always equal to the distance of the luminary from the zenith.

Mr. Nagel, of Trinity College, Oxford, notes that:—"The solar halos on the afternoon of January 29 were very clearly seen in Oxford; the tangential arc to the outer halo was extremely brilliant, and the two mock suns at the extremities of the horizontal diameter of the inner halo were well marked. During part of the time the halos lasted, a whitish incomplete circle was seen about 80° from the sun, and consequently beyond the zenith. This circle seemed to correspond to that first described by Helvelius in 1661."

It is evident from the descriptions given that the parhelia are not, as is sometimes supposed, images of the real sun at all, but only the junctions of two of the circles formed. The upper and the lower parts of these mock suns were drawn out and connected with the first halo, whilst their sides were observed to be drawn out and to merge into the parhelic circle.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE forty-third annual general meeting of the Institution of Mechanical Engineers took place on January 29, 30, and 31, in the theatre of the Institution of Civil Engineers.

The papers down for reading and discussion were as follows: on the compounding of locomotives burning petroleum refuse in Russia, by Mr. Thomas Urquhart, Locomotive Superintendent, Grazi and Tsaritsin Railway, South-East Russia; on the burning of colonial coal in the locomotives on the Cape Government railways, by Mr. Michael Stephens, Locomotive Superintendent; and on the mechanical appliances employed in the manufacture and storage of oxygen, by Mr. Kenneth S. Murray, of London. The latter paper was communicated through Mr. Henry Chapman.

Mr. Urquhart's paper is one of a series of excellent and thoroughly useful descriptions of work done by that gentleman on his railway, and had been for some time promised to the Institution. In order to satisfy himself as to the utility and saving of fuel in compound locomotives, he obtained the sanction of the Government for altering one locomotive by way of experiment. The altered engine was put to work, and the driver was allowed over a month's running to get fully acquainted with the handling in regular service. Comparative trials were then made of the compound against a non-compound locomotive with the same weight of train, on the same days, so as to expose them both to the same circumstances in regard to weather. It was clearly proved that the compound burnt 22 per cent. less of the petroleum refuse used as fuel than the non-compound engine, and the author's experience has left no doubt in his own mind that compound locomotives are the engines of the future in all countries. Mr. Urquhart's results are thoroughly borne out by those obtained in this country by Messrs. Worsdell and Webb. Some engineers suppose that this great economy in fuel is due to the higher working steam pressure, and therefore greater expansion in the compound engines as compared with the non-compound engines.

The paper by Mr. Michael Stephens is a description of the South African coal-fields, their discovery, and general working within the last sixteen years. It appears from the paper that the local coal cannot be burned to advantage without a special arrangement of fire-bars—as may be well imagined, since it contains nearly 30 per cent. of incombustible matter.

Mr. Kenneth S. Murray gives an interesting account of the commercial preparation of oxygen from the atmosphere by means of the alternate heating and cooling of the monoxide of barium. About thirty years ago the eminent French chemist Boussingault made the discovery that, at a temperature of about 1000° F., the monoxide of barium would absorb oxygen readily from the atmosphere, with the resulting formation of the dioxide;

and that at a higher temperature of about 1700° F. the oxygen thus absorbed would be given off again, and the monoxide would apparently be restored to its original condition. The paper clearly describes the machinery required for the manufacture of oxygen by means of barium oxide.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The lecture lists for this term include the following courses:—Prof. Clifton, Magnetism; Mr. Baynes, Thermodynamics; Prof. Odling, Diacidic Olefine Acids; Mr. Veley, Physical Chemistry. Prof. Burdon-Sanderson has resumed his lectures, and Mr. Gotch is treating of the Physiology of Muscle. Dr. Tylor lectures on the Development of Religions.

An open Fellowship in Mathematics at Christ Church has been awarded to Mr. C. H. Thompson, Queen's College, Lecturer in Mathematics at Lampeter. No other mathematical Fellowship has been awarded for about seven years.

The arrangement of the Pitt-Rivers anthropological collection at the Museum is proceeding as rapidly as the constant acquisition of new material allows, and a large portion of the collection is now open for public inspection.

CAMBRIDGE.—At the next meeting of the Cambridge Philosophical Society, on Monday, February 10, the following papers will be read:—

(1) W. Bateson (St. John's), on the perceptions and modes of feeding of fishes.

(2) A. C. Seward (St. John's), notes on Lomatophloios.

(3) S. F. Harmer (King's), on the origin of the embryos in the ovicells of Cyclostomatous Polyzoa.

Prof. Stuart has communicated to the Vice-Chancellor his intention of resigning the Chair of Mechanism and Applied Science before the end of the current academical year.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xii., No. 2 (Baltimore, January 1890).—The number opens with the concluding part of Mr. Forsyth's paper on "Systems of Ternariants that are Algebraically Complete" (pp. 115–160). It is illustrated with numerous tables and closed with a useful abstract of contents.—In the following memoir (pp. 161–190), by Prof. Franklin, on "Some Applications of Circular Co-ordinates," the author investigates, with the aid of these co-ordinates, some interesting theorems relating to the orientation of systems of lines given in a recent volume (vol. x. p. 258) by M. Humbert. Several further illustrations are given, and the memoir closes with a discussion of the curve given by the equation $\sin x dx = \sin y dy$.—Mr. F. N. Cole writes (pp. 191–212) on "Rotations in Space of Four Dimensions." The present article is preliminary to a second paper on groups of rotations in four-dimensional space which is to follow.

Bulletins de la Société d'Anthropologie, tome xii., série iii., fasc. 3 (Paris, 1889).—Continuation of M. Dumont's paper on the natality of Paimpol, in which he treats at great length of the causes which influence the ratio of marriages contracted in every hundred of the population in the maritime districts of Brittany, and of the number of children born in each family. In both these respects the means rank amongst the lowest for all France. One cause for this may be the preponderance of women over men, a large number of the latter being engaged as seamen, or taking part in the Iceland and other distant fisheries. Another factor in this problem is probably the subdivision of property among all the members of a family, who in the peasant and small burgher classes, not uncommonly remain together all their lives, and avoid marriage in the fear of diminishing their individual shares of the patrimony. This, coupled with the repugnance, so common among the French peasantry, against large families, leads indirectly to late marriages or to celibacy, and has thus exercised a baneful influence on the normal increase of the population.—An essay on the classification of human races, based entirely on physical characters, by M. Denniker. Believing in the long persistence of types in spite of the constant intermixture of races, the author thinks that it is only by a careful study of the typical characteristics in a so-called ethnic group that we can arrive at any correct idea of the affinities between different races. In an elaborate synoptical table he enumerates the thirteen races which he proposes for his classification, adding separate remarks on the varieties of each.—The dog, by M. G. de Mortillet. Assuming from negative evidence the non-existence of the dog in the Quaternary age, the author traces his presence onwards from the Kjökkenmöddings, in which abundant remains of this animal are to be found. Passing from the prehistoric ages in Europe he considers at length the evidence that can be advanced of the existence of several varieties of the dog among the Egyptians, and later on among the ancient Greeks and Romans; and in the fact of the innumerable varieties of *Canis domesticus*, M. de Mortillet believes we have one of the most conclusive proofs of evolution.—Observations on the skeletons of two young orangs, by M. Hervé.—Pre-Columbian ethnography of Venezuela, by Dr. Marcano. The most interesting report in this treatise is that referring to the Grotto de Cerro de Luna, owing to the almost absolute certainly that it had never been entered since Guiana was first visited by white men. Here Dr. Marcano recovered fifty-two male, and forty-three female skulls, with five of children, together with numerous long bones. Among these skulls many were painted red, and others had obviously been embalmed. The general mean of their cephalic index was 79, while the facial characters were mesorrhinic and prognathic.—On correlative variations in the biceps, by M. G. Hervé.—A report of the Seventh Conference on Transformism, by M. M. Duval. The author here gives an interesting biographical notice of the great French *savant* Lamarck, entering at the same time fully into the character and scope of his researches, and showing how far his views differed from, or approximated to, those of Darwin. As a *résumé* of what Lamarck attempted on the same lines of inquiry so successfully followed by Darwin, M. Duval's report presents much interest for the English reader.—On the menhirs of Morbihan, by M. Gaillard.—On the discovery of Robenhausian flint implements near Macon, by M. Lafay.—Comparison of three sub-species of man, by M. Lombard.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 23.—"On a Photographic Method for determining Variability in Stars." By Isaac Roberts, F.R.A.S. Communicated by Prof. J. Norman Lockyer, F.R.S.

Some of the uncertainties which necessarily attend the determination of variability in the brightness of stars by eye observations are removed by the application of photographic methods, and particularly by that of giving two or more exposures of the same photographic plate to a given sky space, with intervals of days or weeks between each exposure.

In this way any errors caused by atmospheric, actinic, or chemical changes, together with those due to personal bias, are eliminated, and the study of stellar variability can be pursued under conditions that admit of the necessary exactitude.

As an illustration of the applicability of this dual photographic method, the enlargement on paper from the negative is now submitted. It shows the results obtained by two exposures of the same plate to the sky in the region of the great nebula in Orion. The first exposure was of two hours' duration on January 29, and the second of two and a half hours on February 3, 1889. The stellar images formed during the two exposures are 0·0122 of an inch apart, measured from centre to centre, and therefore comparable with each other in the field of a microscope. When the images are examined in the manner thus indicated, and their diameters also measured by means of a suitably made eye-piece micrometer, it is found that at least ten of the photographed stars, the magnitudes of which are estimated to range between the 7th and 15th, have changed to a considerable extent in the short interval of five days.

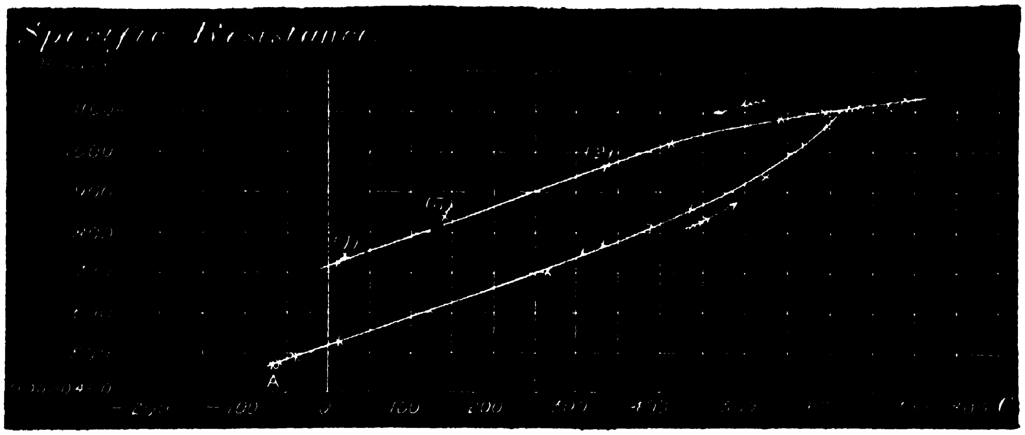
The ten stars referred to are to be found within an area of less than two square degrees of the sky, and in the table given are the co-ordinates of their positions with reference to θ Orionis. The measurements of the diameters of their photo-images on a scale of 0·00002 of an inch are also given.

"Physical Properties of Nickel Steel." By J. Hopkinson, D.Sc., F.R.S.

Mr. Riley, of the Steel Company of Scotland, has kindly sent me samples of wire drawn from the material concerning the magnetic properties of which I recently made a communication

to the Royal Society.[1] As already stated, this material contains 25 per cent. of nickel and about 74 per cent. of iron, and over a range of temperature from something below freezing to 580° C. it can exist in two states, magnetic and non-magnetic.

The wire as sent to me was magnetizable as tested by means of a magnet in the ordinary way. On heating it to a dull redness, it became non-magnetizable, whether it was cooled slowly or exceedingly rapidly by plunging it into water. A quantity of the wire was brought into the non-magnetizable state by heating it, and allowing it to cool. The electric resistance of a portion of this wire, about 5 metres in length, was ascertained in terms of the temperature; it was first of all tried at the ordinary temperature, and at temperatures up to 340° C. The specific resistances at these temperatures are indicated in the curve by the numbers 1, 2, 3. The wire was then cooled by means of solid carbonic acid; the supposed course of change of resistance is indicated by the dotted line on the curve; the actual observations of resistance, however, are indicated by the crosses in the neighbourhood of the letter A on the curve. The wire was then allowed to return to the temperature of the room, and was subsequently heated, the actual observations being shown by crosses on the lower branch of the curve; the heating was continued to a temperature of 680° C., and the metal was then allowed to cool, the actual observations being still shown by crosses. From this curve, it will be seen that in the two states of the metal, magnetizable and non-magnetizable, the resistances at ordinary temperatures are quite different. The specific resistance in the magnetizable condition is about 0·000052, in the non-magnetizable condition it is about 0·000072. The curve of resistance in terms of the temperature of the material in the magnetizable condition has a close resemblance to that of soft iron, excepting that the coefficient of variation is much smaller, as, indeed, one would expect it to be in the case of an alloy; at 20° C. the coefficient is about 0·00132, just below 600° C. it is about 0·0040, and above 600° it has fallen to a value less than that which it had at 20° C. The change in electrical resistance effected by cooling is almost as remarkable as the change in the magnetic properties.



Samples of the wire were next tested in Prof. Kennedy's laboratory for mechanical strength. Five samples of the wire were taken which had been heated and were in the non-magnetizable state, and five which had been cooled and were in the magnetizable state. There was a marked difference in the hardness of these two samples; the non-magnetizable was extremely soft, and the magnetizable tolerably hard. Of the five non-magnetizable samples the highest breaking stress was 50·52 tons per square inch, the lowest 48·75; the greatest extension was 33·3 per cent., the lowest 30 per cent. Of the magnetizable samples, the highest breaking stress was 88·12 tons per square inch, the lowest was 85·76; the highest extension was 8·33, the lowest 6·70. The broken fragments, both of the wire which had originally been magnetizable and that which had been non-magnetizable, were now found to be magnetizable. If this material could be produced at a lower cost, these facts would have a very important bearing. As a mild steel the non-magnetizable material is very fine, having so high a breaking stress for so great an elongation at rupture. Suppose it were used for any purpose for which a mild steel is suitable on account of this considerable elongation at rupture, if exposed to a sharp frost its properties would be completely changed—it would become essentially a hard steel, and it would remain a hard steel until it had been heated to a temperature of about 600° C.

Geological Society, January 22.—W. T. Blanford, F.R.S., President, in the chair.—The following communication was read:—On the crystalline schists and their relation to the Mesozoic rocks in the Lepontine Alps, by Prof. T. G. Bonney, F.R.S. In the debate upon the paper on two traverses of the crystalline rocks of the Alps (read December 5, 1888) it was stated that rocks had been asserted on good authority to exist in the Lepontine Alps, which contained Mesozoic fossils, together with garnets, staurolites, &c., and thus were undistinguishable from crystalline schists regarded by the author as belonging to the presumably Archæan *massifs* of that mountain-chain. In reply the author stated that he regarded this as a challenge to demonstrate the soundness or unsoundness of the hypothesis to which he had committed himself. The present paper gives the result of his investigations, undertaken in the month of July 1889, in company with Mr. James Eccles, to whom the author is deeply indebted for invaluable help. The paper deals with the following subjects:—(1) *The Andermatt Section.* By the geologists aforesaid, a highly crystalline white marble which occurs on the northern side of the Urserenthal trough, at and above Altkirch, near Andermatt, is referred to the Jurassic series (members of which undoubtedly occur at no great distance, almost on the same line of strike). The author describes the relation of the marble to an adjacent black schistose slate, and discusses the significance of some markings in the former which might readily be considered as organic, but to which he assigns a different origin. He shows that there are most serious difficulties in regarding these two rocks as members of the same series, and explains the apparent sequence as the result of a sharp and probably broken infold, as in the case of the admitted band of Carboniferous rock at Andermatt itself. That the section is a difficult one on any hypothesis the author admits, but in regard to the former of these, after a discussion of the evidence, he concludes, "that tendered on the spot demands a verdict of 'not proven'—that obtainable in other parts of the Alps, will compel us to add, 'not provable.' (2) *The Schists of the Val Piora.* These schists, already noticed by the author in his Presidential address to the Society in 1886, occur in force near the Lago di Ritom, and consist of two groups—the one dark mica-schists, sometimes containing conspicuous black garnets, banded with quartzites, the other various calc-mica schists; between them, apparently not very persistent, occurs a schist containing rather large staurolites or kyanites. On the north side is a prolongation of the garnet-actinolite (Tremola-) schists of the St. Gothard and then gneiss, on the south side gneiss. There is also some rauchwacké. This rock, at first sight, appears to underlie the Piora schists, and thus to be the lowest member of a trough. If so, as it is admittedly about Triassic in age, the Piora schists would be Mesozoic. The author shows that (1) the latter rocks do not form a simple fold; (2) they are, beyond all question, altered sediments; (3) they have often been greatly crushed subsequent to mineralization; (4) the garnets, staurolites, &c. (if not injured by subsequent crushing) are well developed and characteristic, and are authigenous minerals. (3) *The Rauchwacké and its Relation to the Schist.* (*a*) *The Val Piora Sections:* The author shows that the rauchwacké, which

[1] See Address to the Institution of Electrical Engineers (NATURE, January 23, p. 274).

at first sight seems to underlie the dark mica-schist, is inconstant in position (on the assumption of a stratigraphical sequence); that its crystalline condition does not resemble that of the schist-series, but is rather such as is common in a rock of its age; that it contains mica and other minerals of derivative origin, and in places rock-fragments which precisely resemble members of the Piora schist series. (*b*) *The Val Canaria Section:* This section, described by Dr. Grubenmann, is discussed at length. It is shown that the idea of a simple trough is not tenable, for identical schists occur above and below the rauchwacké; that there is evidence of great pressure, which, however, acted subsequently to the mineralization of the schists; and that in one place the rauchewacké is full of fragments of the very schists which are supposed to overlie it. (*c*) *Nufenen Pass, &c.:* Other cases, further to the west, are described, where confirmatory evidence is obtained as to great difference in age between the rauchewacké and the schists, and the antiquity of the latter. The apparent interstratification is explained by thrust-faulting. (4) *The Jurassic Rocks, containing Fossils and Minerals.* The author describes the section on the Alp Vitgira, Scopi, and the Nufenen Pass. Here indubitable Belemnites and fragments of Crinoids occur in a dark, schistose, somewhat micaceous rock, which is often very full of "knots" and "prisms" of rather ill-defined external form, something like rounded garnets and ill-developed staurolites. These rocks at the Alp Vitgira appear to overlie, and in the field can be distinguished from the black garnet schists. In one place the rock resembles a compressed breccia, and among the constituent fragments is a rock very like a crushed variety of the black-garnet mica-schist. These Jurassic "schists" are totally different from the last-named schists, to which they often present considerable superficial resemblance; for instance, their matrix is highly calcareous, the other rock mainly consisting of silicates. Some of the associated mica may be authigenous, but the author believes much of it and other small constituents to be derivative. There is, however, a mineral resembling a mica, exhibiting twinning with (?) simultaneous extinction, which is authigenous. The knots are merely matrix clotted together by some undefinable silicate, and under the microscope have no resemblance to the "black garnets." The prisms are much the same, but slightly better defined; they present no resemblance to the staurolites, but may be couseranite, or a mineral allied to dipyre. Hence, though there is rather more alteration in these rocks than is usual with members of the Mesozoic series, and an interesting group of minerals is produced, these so-called schists differ about as widely as possible from the crystalline schists of the Alps, and do not affect the arguments in favour of the antiquity of the latter. In short, they may be compared to rather poor forgeries of genuine antiques. Incidentally the author's observations indicate (as he has already noticed) that a cleavage-foliation had been produced in some of the Alpine schists anterior to Triassic times. After the reading of this paper, Dr. Geikie stated that he had sent to Prof. Heim an abstract of the paper read by Prof. Bonney to the British Association at Newcastle, and Dr. Heim had favoured him with a *résumé* of his views on the subject of the present discussion. Having read a translation of this *résumé*, Dr. Geikie complimented the author on his courage in returning to this difficult ground, but, notwithstanding the arguments so skilfully brought forward that evening, he was not convinced of an error on the part of the Swiss geologists. Even the author's own sections gave some countenance to their views, since the dark garnetiferous schists might quite well be part of the same series as the Belemnite-schists. In metamorphic regions there must be some line, on one side of which fossils are recognizable, on the other not so. In the Alps, as Heim and his associates contend, the Belemnite-schists, which have become markedly crystalline, may be less altered portions of masses from which all trace of fossils has been generally obliterated. Remarks were also made by Mr. Eccles, Mr. Teall, Dr. Irving, Prof. Hughes, the Rev. E. Hill, and Prof. Bonney.

Entomological Society, January 15.—Fifty-seventh Annual Meeting.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—An abstract of the Treasurer's accounts, showing that the finances of the Society were in a thoroughly satisfactory condition, was read by Dr. Sharp, one of the Auditors, and the Report of the Council was read by Mr. H. Goss. It appeared therefrom that the Society had lost during the year several Fellows by death and had elected 24 new Fellows; that the volume of Transactions for the year extended to nearly 600 pages, and comprised 23 memoirs, contributed by 20 authors and illustrated by 17 plates; and that the sale of the Society's Transactions and other publications is largely on the increase. It was then announced that the following gentlemen had been elected as Officers and Council for 1890:—President, The Right Hon. Lord Walsingham, F.R.S.; Treasurer, Mr. Edward Saunders; Secretaries, Mr. Herbert Goss and the Rev. Canon Fowler; Librarian, Mr. Ferdinand Grut; and as other Members of Council, Mr. J. W. Dunning, Captain H. J. Elwes, Mr. F. DuCane-Godman, F.R.S., Dr. P. B. Mason, Prof. R. Meldola, F.R.S., Mr. R. South, Mr. Henry T. Stainton, F.R.S., and Mr. Roland Trimen, F.R.S. Lord Walsingham nominated Mr. J. W. Dunning, Captain Elwes and Mr. F. DuCane-Godman, Vice-Presidents for the Session 1890–91, and he then delivered an address. After remarking on the attractive beauty of some of the larger diurnal Lepidoptera, and the brilliant metallic colouring of certain species of Coleoptera, the influence that such magnificent examples of the wealth of design in Nature might have upon artistic taste, and the consequent refinement and increased enjoyment of life, Lord Walsingham referred, in illustration of the practical usefulness of entomological studies, to the successful importation into California of the Australian parasites infesting the scale insect (*Icerya purchasi*), which had proved so noxious to the orange plantations. Through the efforts of Prof. Riley, upwards of 10,000 parasites had been distributed and had since spread very widely, so that in many localities the orange and other trees hitherto thickly infested with this noxious insect had been practically cleared of it by their aid. He also referred to the successful fertilization of red clover in New Zealand by the importation of impregnated queens of the common humble-bee, and to the uses to which the silk produced by various exotic species of Bombycidæ had now been successfully applied. Reference was then made to the investigation instituted by Mr. Francis Galton, F.R.S., and to the experiments of Mr. F. Merrifield, with the view of determining the percentage of hereditary transmission to successive offspring by different generations of successors, and to the valuable auxiliary such experiments and the researches of Prof. Weismann, Mr. Poulton, F.R.S., and others might prove to the study of the laws of heredity, protective resemblance, and natural selection. It was then observed that even if the study of entomology could claim to have conferred no greater benefits upon the human race than to have afforded to many members of our urban population an inducement to improve their minds and recreate their bodies, it would have contributed in no small degree to the sum of human health, happiness, and morality; in connection with these remarks he quoted the words of the Abbé Umhang in the obituary notice of Henri de Peyerimhoff, "J'ai connu plus d'un jeune homme qui s'est passionné pour une branche de l'histoire naturelle, et je n'en ai vu aucun s'écarter du chemin de la vertu et de l'honneur." Attention was then drawn to the enormous numbers of species of Insecta as compared with the numbers of species of other orders of the animal kingdom, and an approximate estimate was made of the extent of the field of entomology, and of its relation to other branches of biological study. In connection with the subject of the principal works in entomology continued or completed during the year, special mention was made of the "Biologia Centrali Americana," by Messrs. Godman and Salvin, and the "Revisio Insectorum Familiæ Mantidarum," by Prof. Westwood. In conclusion, Lord Walsingham referred to the losses by death during the past year of several Fellows of the Society and other entomologists, mention being made of Mr. F. Bond, Dr. Signoret, Mons. Puls, Colonel C. J. Cox, Pastor Holmgren, Dr. Franz Löw, Dr. Karl Venus, and the Rev. J. G. Wood. Votes of thanks having been passed to the President, Secretaries, and Librarian, Lord Walsingham, Mr. H. Goss, Canon Fowler, and Mr. Grut replied.

Linnean Society, January 16.—Mr. J. G. Baker, F.R.S., Vice-President, in the chair.—Mr. Clement Reid exhibited and made some remarks upon a collection of fruit of *Trapa natans*, from the Cromer Forest bed at Mundesley.—Mr. J. G. Baker exhibited and described a collection of cryptogamic plants from New Guinea, upon which Mr. A. W. Bennett and Captain Elwes made some critical remarks.—In the absence of the author, Mr. A. Barclay, a paper was read by Mr. B. D. Jackson on the life-history of a remarkable Uredine on *Jasminum grandiflora*. A discussion ensued in which Mr. A. W. Bennett and Prof. Marshall Ward took part.—This was followed by a paper from Mr. Edward E. Prince, on certain protective provisions in some larval British Teleosteans.

Royal Microscopical Society, January 8.—Rev. Dr. Dallinger, F.R.S., Vice-President, in the chair.—Mr. T. F. Smith exhibited to the meeting, by means of the oxyhydrogen lantern, a series of photomicrographs of various diatoms taken with Zeiss's apochromatic objectives and projection eye-pieces, giving powers of 1000 to 7500 diameters. At the conclusion of the exhibition Mr. Smith presented the series of slides—52 in number—to the Society for future use and reference.—Mr. T. C. White exhibited a specimen of a parasite found in the cockroaches which infest sugar-ships; also a slide containing bacilli in large numbers from a urinary deposit.—A paper by Dr. R. L. Maddox, on a small glass rod illuminator, was read.—Owing to the lateness of the hour, the reading of papers by Mr. Michael and Dr. Czapski was postponed until the March meeting.

Chemical Society, January 16.—Dr. W. J. Russell, F.R.S., in the chair.—The following papers were read:—A new method of estimating the oxygen dissolved in water, by Dr. J. C. Thresh. The process is based on the fact that whereas, in the absence of oxygen, nitrous acid and hydrogen iodide interact, forming iodine, water, and nitric oxide, in the presence of oxygen the nitric oxide becomes re-oxidized, and, serving as a carrier of the oxygen, brings about an additional separation of iodine, equivalent in amount to the oxygen present; hence, deducting the amount of iodine liberated by the nitrous acid and by the oxygen dissolved in the solutions used from the total amount, the difference will be that corresponding to the oxygen dissolved in the water examined. The apprratus required is a very simple one, the analytical operations are conducted in an atmosphere of coal gas, and the results in the case of freshly distilled water agree closely with those recently published by Sir H. E. Roscoe and Mr. Lunt (Chem. Soc. Trans., 1889, 552).—Note on a milk of abnormal quality, by Mr. F. J. Lloyd. The author gave the results of an examination of the milk of two cross-bred shorthorns, and called attention to the abnormally low proportion of solid constituents other than fat.—The sulphates of antimony, by Mr. R. H. Adie.

Zoological Society, January 14.—Prof. A. Newton, F.R.S., Vice-President, in the chair.—The Secretary read a report on the additions that had been made to the Society's menagerie during the month of December 1889.—Mr. Sclater exhibited and made remarks on a specimen of a very singular duck from North-East Asia, apparently referable to the genus *Tadorna*, sent to him for determination by Dr. Lütken, of Copenhagen. After a careful examination Mr. Sclater was inclined to think that it was probably a hybrid between *Tadorna casarca* and *Querquedula falcata*.—Mr. Sclater exhibited and made remarks on a set of small birds' bones obtained from beneath some deposits of nitrate in Southern Peru, transmitted to the Society by Prof. W. Nation.—Mr. David Wilson-Barker exhibited and made remarks on some specimens of Teredos taken from submarine telegraphic cables off the Brazilian coast.—Prof. F. Jeffrey Bell exhibited and made remarks on some living specimens of *Bipalium*, transmitted to the Society by the Rev. G. H. R. Fisk, of Capetown.—A communication was read from Mr. R. Lydekker, containing an account of a new species of extinct otter from the Lower Pliocene of Eppelsheim. The author described part of the lower jaw, which he had previously referred to *Lutra dubia*, from the deposits indicated. Having, however, now seen a cast of the type of the latter, he found that the present specimen indicated a distinct species, for which the name *L. hessica* was proposed.—A communication was read from Prof. Bertram C. A. Windle and Mr. John Humphreys, on some cranial and dental characters of the domestic dog. The paper was based on the results of the measurements of a large number of dogs' skulls of various breeds. Its object was to ascertain whether cranial and dental characteristics afforded sufficient information to permit of a scientific classification of the breeds, or would throw any light upon their origin. The conclusion so far arrived at was that interbreeding had been so extensive and complicated as to make it impossible to distinguish the various forms scientifically from the characters examined. Several points with regard to the shape of head and palate and the occasional occurrence of an extra molar were also touched upon.—Mr. G. A. Boulenger read the fourth of his series of contributions to the herpetology of the Solomon Islands. The present memoir gave an account of the last collection brought home by Mr. C. M. Woodford. Besides known species, this collection contained examples of a new snake, proposed to be called *Hoplocephalus elapoides*.—A second paper by Mr. Boulenger contained a list of the reptiles, batrachians, and freshwater fishes collected by Prof. Moesch and Mr. Iversen in the districts of Delhi and Langkat, in North-Eastern Sumatra.—Dr. Günther, F.R.S., read a paper entitled "A Contribution to our Knowledge of British Pleuronectidæ." The author described the true *Arnoglossus grohmanni*, a Mediterranean scald-fish, recently discovered by the Rev. W. S. Green on the Irish coast, and quite distinct from *Arnoglossus lophotes*. Dr. Günther also stated that the Mediterranean lemon-sole (*Solea lascaris*) was specifically identical with the British species (*Solea aurantiaca*), but was distinct from that of the Canary Islands and Madeira (*Solea scriba*); and gave it as his opinion that the Mediterranean *Solea lutea* and British *Solea minuta* cannot be separated by any constant character.

EDINBURGH.

Royal Society, January 6.—Lord Maclaren, Vice-President, in the chair.—Bailie Russell read an obituary notice of the late Sir James Falshaw, Bart.—Prof. Tait read a paper on the effect of friction on vortex-motion.—Dr. A. Bruce described a connection (hitherto undescribed) of the inferior olivary body of the medulla oblongata, which has a function in the maintenance of equilibrium of the body.—Dr. W. H. Perkin read a paper on the internal condensation of some diketones.—A photograph of a group of sun-spots and of the surface of the sun was presented by Mr. James Naismith. The photograph was from a drawing made in 1864.

PARIS.

Academy of Sciences, January 27.—M. Hermite in the chair.—On clasmatocytes, by M. L. Ranvier. The author gives this name (from κλάσμα, fragment, and κύτος, cell) to certain elements which are easily detected under the microscope in the thin connective membranes of the vertebrates when they are prepared by a process here described. They are not migratory cells, but have their origin in the leucocytes, or lymphatic cells, though it is not to be supposed that all leucocytes develop into clasmatocytes.—On the theorem of Euler in the theory of polyhedrons, by M. de Jonquières. The paper deals with Lhuilier's objection, accepted by Gergonne, against the generalization of Euler's formula, which is shown to be applicable to all polyhedrons, whether convex or not. It is further placed beyond doubt that Euler not only enounced, but gave a full demonstration of the formula in question.—On the roots of an algebraic equation, by Prof. A. Cayley. Assuming $\int(u)$ to be a rational and integral function, with real or imaginary coefficients, of the n order; and supposing that the equation $\int'(u) = 0$, of the order $n - 1$, has $n - 1$ roots, then it is shown that the equation $\int(u) = 0$ will have n roots. The demonstration rests on the same principles as those of Gauss and Cauchy.—Researches on the cultivation of the potato, by M. Aimé Girard. The author communicates the results of his experiments, continued for three years at the Ferme de la Faisanderie, Joinville-le-Pont, with the variety of the potato known as Richter's Imperator, which is shown to yield a far larger crop of starch-bearing tubers than any other variety cultivated in France. The paper was supplemented by some remarks by M. P. P. Dehérain, who stated that his own experiments fully confirmed those of M. Girard. There could be no doubt as to the great superiority of Richter's Imperator, especially as a starch-producing tuber.—Remarks on the *Annuaire du Bureau des Longitudes* for 1890, by M. Faye. In presenting a copy of this valuable annual for 1890, M. Faye remarked that the astronomic section of the work became more important every year. The present volume contains a table of the planetary phenomena, the most accurate available data for the variable stars, a catalogue of the chief stars whose magnitudes correspond to Pickering's photometric scale, papers on the use of the aneroid barometer, on the elasticity of solids and the neutral temperature of thermo-electric couples, together with the magnetic elements for France and its seaports on January 1, 1890, and at various Mediterranean stations for 1887.—On the simply rational transformations of algebraic surfaces, by M. Paul Painlevé. In this paper the author extends to the transformations in question M. Picard's method relative to the birational transformations of algebraic surfaces.—On the substitution of the salts in mixed solutions, by M. A. Etard. In his previous researches the

author determined the lines of complete solubility for a mixture of potassium and sodium chlorides, varying the quantity of the *metals* saturated by the same metalloid as a function of the temperature. He studies the reverse case here, determining the results when in a solution of the same metal the *metalloids* are varied.—On the different states of iodine in solution, by MM. Henri Gautier and Georges Charpy. Iodine solutions are usually divided into two classes—brown (alcohol, ether, &c.) and violet (sulphur of carbon, chloroform, benzine, &c.). The molecular weights have been determined by Raoult's method, and results were obtained varying from 330 to 489, according to the solvent; Loeb's results are thus confirmed and amplified.—Calorimetric study of the phosphites and pyro-phosphite of soda, by M. L. Amat. These researches fully confirm the author's previous conclusion that the acid phosphite of soda, $PO_3H.NaH$, may, by the simple process of drying, lose water and become transformed into pyrophosphite of soda, a substance differing in many of its properties from the acid phosphite.—A study of the pneumococcus occurring in the fibrine pneumonia consecutive to *la grippe* (influenza), by MM. G. Sée and F. Bordas. From these clinical researches, made on a large number of patients in the Hôtel-Dieu, the authors conclude that pneumonia is not only a local affection caused by infection, but that it is itself infecting in the sense that it may invade other organs.—Papers were read by M. Chr. Bohr, on pulmonary respiration; by M. Abel Dutartre, on the poison of the land salamander; by M. Ch. Musset, on "selenotropism" (influence of moonlight on plants); by M. A. de Schulten, on the artificial reproduction of malachite all but identical in density, hardness, and crystallization with the natural stone; by M. A. de Grossouvre, on the presence of Alpine fossils in the Callovian formation of the west of France; and by M. Ch. V. Zenger, on the magnetic storms and auroræ boreales of the years 1842-57.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, FEBRUARY 6.

ROYAL SOCIETY, at 4.30.—A New Theory of Colour-blindness and Colour-perception: Dr. Edridge Green.—Memoir on the Symmetrical Functions of the Roots of Systems of Equations: Percy A. MacMahon, Major R.A.

LINNEAN SOCIETY, at 8.—On the Stamens and Setæ of Scirpeæ: C. B. Clarke, F.R.S.—On the Flora of Patagonia: John Ball, F.R.S.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—The Oxides of Nitrogen: Prof. Ramsay, F.R.S.—Studies on the Constitution of Tri-Derivatives of Naphthalene: Dr. Armstrong and W. P. Wynne.—On the Action of Chromium Oxychloride on Nitrobenzole: G. G. Henderson and J. Morrow Campbell.

ROYAL INSTITUTION, at 3.—Sculpture in Relation to the Age: Edwin Roscoe Mullins.

FRIDAY, FEBRUARY 7.

PHYSICAL SOCIETY, at 5.—Annual General Meeting.—On Galvanometers: Prof. W. E. Ayrton, F.R.S., T. Mather, and W. E. Sumpner.—On a Carbon Deposit in a Blake Telephone Transmitter: F. B. Hawes.

GEOLOGISTS' ASSOCIATION, at 7.30.—Annual General Meeting.—Notes on the Nature of the Geological Record: The President.

SOCIETY OF ARTS, at 5.—The Utility of Forests and the Study of Forestry: Dr. Schlich.

INSTITUTION OF CIVIL ENGINEERS, at 7.30.—Reclamation of Land on the River Tees: Colin P. Fowler.

ROYAL INSTITUTION, at 9.—The London Stage in Elizabeth's Reign: Henry B. Wheatley.

SATURDAY, FEBRUARY 8.

ROYAL BOTANIC SOCIETY, at 3.45.

ROYAL INSTITUTION, at 3.—The Natural History of the Horse, and of its Extinct and Existing Allies: Prof. Flower, C.B., F.R.S.

MONDAY, FEBRUARY 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Search and Travel in the Caucasus; an Account of the Discovery of the Fate of the Party lost in 1888: Douglas W. Freshfield (illustrated by Photographs by Signor V. Sella and H. Woolley).

SOCIETY OF ARTS, at 8.—The Electromagnet: Dr. Silvanus P. Thompson.

TUESDAY, FEBRUARY 11.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—Exhibition of some Skulls, dredged by G. F. Lawrence from the Thames, in the Neighbourhood of Kew: Dr. Garson.—Characteristic Survivals of the Celts in Hampshire: T. W. Shore.

SOCIETY OF ARTS, at 8.—Cast Iron and its Treatment for Artistic Purposes: W. R. Lethaby.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Bars at the Mouths of Tidal Estuaries: W. H. Wheeler.

ROYAL INSTITUTION, at 3.—The Post-Darwinian Period: Prof. G. J. Romanes, F.R.S.

UNIVERSITY COLLEGE BIOLOGICAL SOCIETY, at 5.15.—Some Aberrant Coleoptera: S. V. Tebbs.

WEDNESDAY, FEBRUARY 12.

ROYAL MICROSCOPICAL SOCIETY, at 8.—Annual Meeting.—President's Address.

SOCIETY OF ARTS, at 8.—Modern Improvements in Facilities for Railway Travelling: George Findlay.

THURSDAY, FEBRUARY 13.

ROYAL SOCIETY, at 4.30.

MATHEMATICAL SOCIETY, at 8.—Concerning Semi-invariants: S. Roberts, F.R.S.—Ether-Squirts: Prof. K. Pearson.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.

ROYAL INSTITUTION, at 3.—The Three Stages of Shakspeare's Art: Rev. Canon Ainger.

FRIDAY, FEBRUARY 14.

ROYAL ASTRONOMICAL SOCIETY, at 3.—Anniversary Meeting.

ROYAL INSTITUTION, at 9.—Problems in the Physics of an Electric Lamp; Prof. J. A. Fleming.

SATURDAY, FEBRUARY 15.

ROYAL INSTITUTION, at 3.—Electricity and Magnetism: Right Hon. Lord Rayleigh, F.R.S.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

RELIGIOUS INSTITUTIONS OF THE SEMITES.

Lectures on the Religion of the Semites. The Fundamental Institutions. By W. Robertson Smith. (Edinburgh: Black, 1889.)

THE volume before us contains the first series of lectures on "the primitive religions of the Semitic peoples, viewed in relation to other ancient religions, and to the spiritual religion of the Old Testament and of Christianity," which the Trustees of the Burnett Fund asked Prof. Robertson Smith to deliver at Aberdeen in the year 1887. As may be readily imagined, the selection of Prof. R. Smith as lecturer on the subject which, of all men in England, he had made peculiarly his own, was approved of by Semitic scholars and by the more liberal-minded of the clergy of all denominations. There were and are, of course, many who will view the publication of these lectures in a book form with anything but favour; still it is quite certain that they must, if honestly read and candidly thought over, bring many of this class over to the view, which is gaining ground with great rapidity, that, if the Hebrew Scriptures are to be properly understood by us, and their value accurately gauged, we must bring to their consideration the same amount of common-sense, the same critical investigation, and the same weighing of evidence, which we should bring to bear upon any piece of general history. The Bible is a unique work, and is the production of many writers who lived at different periods. In it we have a mixture of historical facts fused with legend, poetry, folk-lore, stories, and traditions, deeply devotional religious hymns, prophecies, and descriptions of scenes in the life and history of the sons and descendants of Abraham. Anyone who knows the Oriental character will understand at once why the book is such a favourite with the Eastern Semites, and will see that it is precisely the kind of work which their writers could not help producing; it is the greatest mistake possible, however, to assume that the book could only be the production of a certain branch of the Semitic race. This is what has been thought for centuries by clergy and laity alike, and as a result its value has been much underrated and its evidence only partly understood; also, for hundreds of years the value of the Hebrew text from the point of view of comparative philology was rendered useless because a powerful section of the Church declared that the vowel-points were an integral part of the text itself, and not an addition to it made by the Rabbis of Tiberias because the true pronunciation of the language was dying out and was not generally understood. The Bible has lost nothing in the eyes of scholars because it has been proved that the vowel-points are not fourteen hundred years old, and that the learned men who added the points made mistakes themselves! It is hard to say what provoked the intense opposition of certain sects of the Church a few years ago to historical research as applied to the New Testament. It may be that the *manner* in which the German philologists and commentators carried on their investigations, and expressed their opinions, caused the narrow-minded, and we may add unlearned, theologians of the English Church to abhor and detest all such works; nevertheless, we venture to believe that, in spite of all the so-called destructive criticism of Kuenen and Wellhausen, the Bible has gained more by the labours of the critical school, of which these two scholars are brilliant examples, than it has lost. It is but a few years since Prof. Robertson Smith defended his views on historical research as applied to the Old Testament before the courts of his Church, in which bigotry and ignorance of modern research were curiously blended, and in a very few years it will be difficult to believe that such a trial—the only result of which was the loss to his Church of its most learned member—ever took place.

The lectures printed in the first volume of Prof. Robertson Smith's work are eleven in number, and they relate to the fundamental institutions of the Semitic race as a whole, viz. sanctuaries, sacrifices, first-fruits, tithes, the blood covenant, fire sacrifices, sacrificial gifts, &c. The introductory lecture explains clearly the method of inquiry into the subject, and states the lines upon which this inquiry is to be based. Practically speaking, Prof. Robertson Smith says:—We have the Bible with its remarkable accounts of the institutions of the ancient Jews, and of the ancestors of these Jews. We want to find out a great deal more about them than is stated in it, because the writers, taking for granted that its readers would understand not only their arguments but the facts which led up to them, and the history and manners and customs of the race to which they belonged, only made sufficient reference to them to make the point under discussion perfectly clear. The Jews were a small nation, belonging to the great Semitic race, which had a great deal in common with the other peoples of the race, viz. Assyrians, Babylonians, the dwellers of Syria, &c., whom we have been taught to look upon as heathen outside the pale of the salvation of the Jewish God. Now the Jews have left behind them fewer remains than any other nation belonging to the great Semitic race; the other nations of this race, however, have left behind them inscriptions, buildings, books, &c., the study of which will cast much light upon the manners and customs of the peoples described in the Old Testament. The last sixty years have made us acquainted with the languages which these people spoke, we have learned the relationships of these nations to each other, we have certain fixed points in their chronology, and we know a great deal about their religion and their public and private life. Let us then compare the records of all these various families of the Semitic race, and see how much they have in common, where they differ, and if possible let us try and find out how they differ. With a mind well stocked by the study of the native records of the great Semitic nations, Prof. Robertson Smith begins this difficult task. At the outset he distinguishes between Judaism, Christianity, and Islam, which he calls *positive* religions, and the systems of ancient heathenism. Each of the positive religions, however, was built upon the beliefs and customs of ancient heathenism, and we can only understand a system of positive religion when we understand the principles of the religion which preceded it. The Hebrews had many religious conceptions and usages in common with many kindred peoples; and as the matter is pithily put by

Prof. Robertson Smith, "those who had no grasp of spiritual principles, and knew the religion of Jehovah only as an affair of inherited usage, were not conscious of any great difference between themselves and their heathen neighbours, and fell into Canaanite and other foreign practices with the greatest facility. . . . Traditional religion is handed down from father to child, and therefore is in great measure an affair of race. Nations sprung from a common stock will have a common inheritance of traditional belief and usage in things sacred as well as profane, and thus the evidence that the Hebrews and their neighbours had a large common stock of religious tradition falls in with the evidence which we have from other sources, that in point of race the people of Israel were nearly akin to the heathen nations of Syria and Arabia." Prof. Robertson Smith, in common with the general opinions of the best scholars, is inclined to place the original home of the Semitic race in the Arabian peninsula, and it is pretty certain that, from time immemorial, the tract of land bounded by the Mediterranean on the west, Persia on the east, the Armenian mountains on the north, and the Indian Ocean on the south, was peopled by tribes who spoke Semitic dialects. It must not be forgotten that the so-called Babylonians had their territory invaded by a horde of warlike but intelligent men from the east who eventually succeeded in imposing upon them the cuneiform writing. After all the nonsense which has been talked during the last few years about the so-called "Hittites" being identical with the Hittites of the Bible, it is refreshing to find a scholar like Prof. Robertson Smith stating plainly that the "Hittites of the Bible . . . were a branch of the Canaanite stock, and that the utmost concession that can be made to modern theories on this subject is that they may for a time have been dominated by a non-Semitic aristocracy." It is as well to say at once that no successful attempt has yet been made to decipher the "Hittite" inscriptions, and none can be made until a bilingual inscription has been found. The "boss" of Tarkondemos is, no doubt, a forgery; but, even granting that it is not, no one can certainly say what or how many of the signs in the centre of the "boss" represent one of the words in cuneiform around it.

Prof. R. Smith is quite right not to place too much trust in the traditions of the Babylonian religion as made known to us by the cuneiform inscriptions. It is true that these are the oldest Semitic inscriptions known to us, but it is to be remembered that the writing itself and many of the religious myths and traditions known to the Babylonians were either forced upon them by, or borrowed from, their conquerors from the east. Just as the Arabic language is the right point to start from in the study of comparative Semitic mythology, so the traditions of the old, heathen inhabitants of Arabia are those which must form the ground-work of any comparative inquiry into the traditions of Semitic religion generally. The remainder of the first lecture is occupied with general statements of an important nature, which no reviewer could do justice to in an ordinary review. Lecture II. describes the primitive Semitic society and its religion; the oldest Semitic communities and their gods; the fatherhood of the gods, and the kinship of gods and men; monarchy and monotheism, &c. Lecture III. discusses the gods, jinn, totems, and Semitic totemism; Lecture IV., holiness, taboo, the sanctuary, and the jealousy of the god; Lecture V., sanctuaries, holy waters, trees, caves, and stones; Lecture VI., sacrifice in all its various forms; Lecture VII., first-fruits, tithes, and sacrificial meals; Lecture VIII., the original significance of animal sacrifice; Lecture IX., the sacrificial efficacy of animal sacrifice, the blood covenant, &c.; Lecture X., the development of sacrificial ritual and fire sacrifices; Lecture XI., the special ideas involved in piacular sacrifices. A series of "additional notes" (A—N) and a good index complete the volume. Prof. Robertson Smith's arguments are sound, and they are carefully reasoned out; but as new material comes to hand some of the details may require alteration. The work deserves the careful study of all scholars who are anxious to meet with a straightforward, unbiassed statement upon the difficult subject of ancient Semitic religion; where it has been necessary to combat opposite opinions, the discussion is carried on with fairness to the scholars concerned, and consequently with credit to the author of these lectures. The works of Kuenen, Wellhausen, and Goldziher, repel, rather than attract, many readers; we do not imagine that any honest seeker after truth, be he theologian or lay reader, will turn away from the perusal of these lectures, having once begun to read them. It is to be hoped that Bible commentators will at once embody in their works the explanations of the large number of Scriptural passages which have, up to the present, been simply not to be understood. It is also to be hoped that Prof. R. Smith will soon be enabled to give to the world the concluding part of his valuable work, the publication of which is a sign of the times in England.

ALGEBRA.

Algebra: an Elementary Text-book for the Higher Classes of Secondary Schools and for Colleges. By G. Chrystal, M.A. Part II. (Edinburgh: Adam and Charles Black, 1889.)

THE work before us is the realization of the hope with which we concluded our notice of the first part (NATURE, vol. xxxiv. p. 614).

The author apologizes for the delay in its appearance. The occupation of a busy life would be to most men a sufficient *raison d'être* for such delay, and to this has been added a further source of delay arising from circumstances of a private character. Students, however, have gained hereby, for the work has grown in the progress of its construction. It has not, "as some one prophesied, reached ten volumes," for this is the concluding volume; but it has, we are told, cost the writer infinitely more trouble than he expected. The first instalment extended to 542 pages; this one, with answers and index of names (which we are glad to have), is comprised in 588 pages. The prominent features of the exposition as to its "singular ability and freshness of treatment" are as conspicuous here as in Part I., and we need not repeat the praise which we accorded to it (*l.c.*).

Let us hearken to Prof. Chrystal, for he always writes to the point:—

"The main object of Part II. is to deal as thoroughly as possible with those parts of algebra which form, to

use Euler's title, an 'Introductio in Analysin Infinitorum.' A practice has sprung up of late (encouraged by demands for premature knowledge in certain examinations) of hurrying young students into the manipulation of the machinery of the differential and integral calculus before they have grasped the preliminary notions of a *limit* and of an *infinite series*, on which all the meaning and all the uses of the infinitesimal calculus are based. Besides being to a large extent an educational sham, this course is a sin against the spirit of mathematical progress. The methods of the differential and integral calculus, which were once an outwork in the progress of pure mathematics, threatened for a time to become its grave. Mathematicians had fallen into a habit of covering their inability to solve many particular problems by a vague wave of the hand towards some generality, like Taylor's theorem, which was supposed to give 'an account of all such things,' subject only to the awkwardness of practical inapplicability. Much has happened to remove this danger and to reduce d/dx and $\int dx$ to their proper place as servants of the pure mathematician. . . . For the proper understanding of this important branch of modern mathematics [*i.e.* function-theory], a firm grasp of the doctrine of limits and of the convergence and continuity of an infinite series is of much greater moment than familiarity with the symbols in which these ideas may be clothed. It is hoped that the chapters on inequalities, limits, and convergence of series [chapters xxiv.–xxvi.], will help to give the student all that is required both for entering on the study of the theory of functions and for rapidly acquiring intelligent command of the infinitesimal calculus. In the chapters in question, I have avoided trenching on the ground already occupied by standard treatises: the subjects taken up, although they are all important, are either not treated at all or else treated very perfunctorily in other English text-books."

No student who masters the present treatise will pass such judgment upon these chapters, or, indeed, upon any part of the work. What the writer aims at, and succeeds in achieving, is thoroughness.

The first part occupied twenty-two chapters; the second part occupies chapters xxiii.-xxxvi.

Following on the lines of our previous notice (*l.c.*), we give a brief analysis of the chapters:—23, permutations and combinations (with applications to binomial and multinomial theorems, distributions and derangements, and the theory of substitutions); 24–26, see extract above; 27, binomial and multinomial theorems for any index: 28, exponential and logarithmic series (with an account, and applications, of Bernoulli's numbers); 29, 30, summation of the fundamental power-series for complex values of the variable, and general theorems regarding the expansion of functions in infinite forms—these are two splendid chapters, which the author says

"may be regarded as an elementary illustration of the application of the modern theory of functions. They are intended to pave the way for the study of the recent works of Continental mathematicians on the same subject. Incidentally, they contain all that is usually given in English works under the title of analytical trigonometry. If anyone should be scandalized at this traversing of the boundaries of English examination subjects, I must ask him to recollect that the boundaries in question were never traced in accordance with the principles of modern science, and sometimes break the canon of commonsense. . . . The timid way, oscillating between ill-founded trust and unreasonable fear, in which functions of a complex variable have been treated in some manuals, is a little discreditable to our intellectual culture. Some expounders of the theory of the exponential function of an imaginary argument, seem even to have forgotten the obvious truism that one can prove no property of a function which has not been defined."

Chapter 30, moreover, closes with "a careful discussion of the reversion of series and of the expansion in power-series of an algebraic function—subjects which have never been fully treated before in an English textbook, although we have in Frost's *curve-tracing* an admirable collection of examples of their use" (this is a work often referred to with high commendation in the text). To resume our analysis, chapter 31 is on the summation and transformation of series in general; 32–34 gives a thorough discussion of continued fractions and their applications; 35 gives numerous general properties of integral numbers; and 36 is on probability, or the theory of averages. In this last chapter the author has "omitted certain matter of doubtful soundness and of questionable utility; and filled its place by what I hope will prove a useful exposition of the principles of actuarial calculation."

The student of the present day knows that "things are not always what they seem," so when he hears that an elementary text-book of algebra occupies more than a thousand octavo printed pages, he is prepared to find that the "elementary" is comparative, and the "algebra" comprises some other subjects, in ordinary parlance, called by other names. He will find the present work most readable, provided he comes to the perusal with the requisite knowledge and ability, and when he has got to the end of the course he will have an excellent foundation for all his after mathematical reading. Prof. Chrystal gives good advice, which we copy. "When you come on a hard or dreary passage, pass it over; and come back to it after you have seen its importance or found the need for it further on. To facilitate this skimming process, I have given, after the table of contents, a suggestion for the course of a first reading." There are numerous "historical notes," which form a conspicuous and useful feature of the whole work.

The author uses the expression (see above) "dreary passage": we have not come across these, but we can certify with regard to the first part, that we have taken it up again and again, and have always found it difficult to rest contented with a brief glance, and the part before us appears, in some respects, to be even more attractive.

FERMENTATION WITH PURE YEAST.

The Micro-organisms of Fermentation, practically considered. By Alfred Jörgensen. Edited from the German by G. Harris Morris, Ph.D., F.C.S., F.I.C., &c. With an Introduction by Horace T. Brown, F.C.S., F.I.C. (London: F. W. Lyon, 1889.)

DURING the past ten years in which the investigation of micro-organisms and their functions has been so actively pursued there has been a conspicuous absence of any work dealing with the progress made in our knowledge of those particular forms which are of industrial importance. Thus whilst numerous text-books in various languages have appeared embodying the latest discoveries in the relationship of micro-organisms to disease, the only noteworthy treatise on the technological side of

bacteriology since Pasteur's "Etudes sur le Vin, le Vinaigre, et la Bière," the last of which was published in 1876, is Alfred Jörgensen's "Micro-organismen der Gährungsindustrie" (1886), of which the volume before us is an edited translation. This lack of text-books is doubtless in great measure due to the industrial aspects of micro-organisms having been comparatively neglected during the time that Pasteur, Koch, and their numerous disciples have been busily engaged in the investigation of questions of still more absorbing human interest. But whilst the great majority of bacteriologists have during this past decade been thus occupied in establishing or endeavouring to establish the connection between numerous diseases and specific organisms, a few more silent workers have been patiently engaged upon the less sensational though no less arduous task of placing the fermentation industries on a more scientific basis, adding in fact to the structure which had been commenced by Pasteur in his "Etudes" referred to above. The foremost in this field of research has unquestionably been Christian Hansen of the now world-famed Carlsberg Laboratory near Copenhagen, and to a concise and most lucid description of whose successful labours the present volume is chiefly devoted. The principal addition which has been made to our knowledge of the fermentation organisms by Hansen has been the precise characterization of a number of different "races" of yeast and the determination of the specific features of the fermentation induced by each particular race. Thus whilst Pasteur attributed the various diseases in wine and beer to the presence of organisms other than yeast, Hansen has shown that certain races of yeast itself are capable of bringing about most serious disturbances in the fermentation process. The lines on which Hansen has differentiated these several races of yeast, and the methods by which their pure culture may be effected are clearly though briefly described in this work, with which latest developments of brewing technology, both the author and translator have already identified themselves in the past.

The influence which has been exerted by the researches of Pasteur and Hansen on the practical conduct of the fermentation industries is quite analogous to that which has resulted in surgery from the investigations of Lister and Koch, in both cases the principle of rigid scientific cleanliness has become the order of the day. Thus we read, "the air in the fermenting-room may contain a world of germs which, in the fermentation industries, bring with them the most calamitous results; it is, however, possible to obtain air free from these invisible germs, and it admits of no doubt that, on the one hand, the purification of the air in the fermenting-room by passing it through a salt-water bath, and, on the other hand, the most rigidly executed order and cleanliness in the cellars of the Old Carlsberg brewery, stand in direct relation to the results."

From a practical point of view, the chief merit due to Hansen is that he has not only shown how pure growths of yeast may be obtained in the laboratory, but that he has further devised methods by which these pure cultures may actually be employed on the largest brewery scale. This brewing with pure yeast has already assumed very large dimensions on the Continent where a continually increasing number of breweries receive regular supplies of pure material. We have ourselves visited the laboratories of the Wissenschaftliche Stationen für Brauerei und Brennerei at Berlin and at Munich, and can testify to the impressiveness of witnessing the careful preparation on the manufacturing scale of different forms of pure yeast, each possessed of specific fermenting properties, which are then transmitted to various parts of Europe according to the special requirements of different breweries. These experimental brewing-stations, like so many other similar institutions on the Continent, are directly or indirectly subsidized by the State and number amongst their staff men of universal reputation in their particular departments. As we should anticipate, this method of scientific brewing with pure yeast has so far taken no root in this country, although we are glad to know that the translator, along with Mr. Horace Brown, has for some time past been engaged upon its experimental trial, and we learn from the latter in his introduction to this book "that, in a more or less modified form, pure yeast culture will play a very important part in the brewing of the future in this country."

This little work, which is condensed into 166 pages, and profusely illustrated and provided with an admirable bibliography, should receive the most careful attention from practical men, for whom it is mainly intended. Even the purely scientific student will find much in its pages that should prove of service to him.

PERCY F. FRANKLAND.

OUR BOOK SHELF.

An Epitome of the Synthetic Philosophy. By F. Howard Collins, with a Preface by Herbert Spencer. (London: Williams and Norgate, 1889.)

THE aim and scope of this work cannot be more tersely or more accurately conveyed than by quoting *in extenso* the "compiler's preface."

"The object of this volume is to give in a condensed form the general principles of Mr. Herbert Spencer's Philosophy as far as possible in his original words. In order to carry out this intention each section (§) has been reduced, with but few exceptions, to one-tenth; the five thousand and more pages of the original being thus represented by a little over five hundred. The Epitome consequently represents 'The Synthetic Philosophy' as it would be seen through a diminishing glass: the original proportion holding between all its varied parts.

"Should this volume lead the general reader to a better acquaintance with Mr. Spencer's own works, I shall feel amply repaid for my labour.

"My warmest thanks are due to Mr. Spencer for his invaluable preface; and also to Miss Beatrice Potter, and Mr. Henry R. Tedder, F.S.A., the able and accomplished secretary and librarian of the Athenæum Club, for their valuable suggestions while the work has been in progress."

The desirability of such an undertaking, supposing it to have been successfully accomplished, is both manifest and manifold. Mr. Spencer's works are so voluminous that it is impossible to acquire a knowledge of his system of philosophy as a whole without devoting to it an expenditure of time which is practically impossible for most men who are not specially engaged in philosophic studies. Moreover, even to a reader who is thus specially engaged, and who therefore desires fully to master this system, no small difficulty is experienced from the fact that hitherto there has not been so much as an index to guide his

studies through these reams and reams of paper. Consequently, the first class of readers have hitherto for the most part been satisfied to gain their knowledge of Spencer through the "Cosmic Philosophy" of Fiske, while the latter class have experienced a hitherto hopeless difficulty in refreshing their memories upon particular points, or in finding passages to which they may wish to refer in publications of their own. Speaking for ourselves, we are conscious of often having done a negative injustice to Mr. Spencer on this account, simply because, in order to avoid the possibility of any positive injustice in the way of misrepresentation, we have deemed it wisest not to allude to him at all.

Now, the epitome which Mr. Howard Collins has supplied so admirably satisfies all the requirements of the case that henceforth the general reader will be able to acquire a clear knowledge of Mr. Herbert Spencer's philosophy in one-tenth of the time that it has hitherto been necessary to expend, while—as Mr. Spencer himself observes in his highly commendatory preface—more serious students will find that "a clear preliminary conception is more readily obtained from a small outline-map than from a large one full of details." Lastly, for all purposes of reference, this epitome leaves nothing to be desired; for not only does it run parallel with the original—chapter by chapter and section by section—but it is also furnished at the end with an alphabetical index of subject-matter: so that, if a man is writing upon any of the innumerable topics which Mr. Spencer has handled, he can immediately ascertain all that Mr. Spencer has said with regard to them.

For these reasons we cordially recommend this most painstaking epitome to every class of readers; and we cannot doubt that its publication will greatly promote the diffusion of Mr. Spencer's thought in all the English-speaking communities of the world. G. J. R.

The Earth and its Story. Edited by Robert Brown, Ph.D., F.L.S. (London: Cassell and Co., 1889.)

THE continued publication of good and popularly written scientific works is one of the most gratifying signs of the times; it testifies, in no uncertain manner, to the growth of a taste for scientific knowledge in the mind of the general public, and hence is a matter of congratulation.

Of all the sciences none may perhaps be made more interesting than physical geography, or its modern equivalent physiography. The desire to know something about the earth's position in the universe, its formation, and its inhabitants, is and always has been innate in man, and we are glad, therefore, to welcome works that may satisfy this craving after light. The one before us deals in a comprehensive manner with the geographical distribution of plants and animals, and the agents concerned in their dispersion; with the physics of the sea, waves, currents, and tides; with terrestrial magnetism; climate and the causes affecting its distribution; rainfall and precipitation in general. A considerable amount of space is given to descriptions of geological formations and the fossils they contain, whilst ideal landscapes with restored animals are plentifully figured. We regret, however, that only a very meagre description is given of the earth as a planet. It must be remembered that astronomy is a very important part of physiography, even when looked at from a utilitarian point of view. The reason why the movements of the heavenly bodies have been studied from time immemorial is that a knowledge of them was necessary in order to meet the vicissitudes of life, and even before primitive man had inquired into the constitution of the earth he had arrived at crude conceptions as to the constitution of the universe from uncritical observations of celestial phenomena. The priority of these conceptions demonstrates their importance, and therefore, in a work intending to convey earth knowledge, the verification of the earth's rotation and revolution and the determination of its true size and shape should certainly be included. The measurements of arcs of meridian, whereby the exact size and shape of the earth may be found, are easy to describe, and preferable to the proofs of the earth's rotundity known in the time of Peate; besides which, such investigations essentially belong to physical geography. But, excepting these omissions, the work is one of sterling value; it is profusely illustrated, each of the two volumes containing twelve coloured plates and about 270 woodcuts, and the explanatory text is very readable and interesting throughout. Such a production will naturally gravitate to the free public libraries and similar institutions, and will be of great use in extending scientific knowledge.

Steam. By William Ripper, Professor of Mechanical Engineering in the Sheffield Technical School. (London: Longmans, Green, and Co., 1889.)

THIS volume consists of an elaboration of notes of lectures given by the author to an evening class of young mechanical engineers. For its size, it contains much useful information; and the simplicity of expression, and the absence of elaborate calculation, throughout the chapters help to make it suitable for elementary classes. The author gives special prominence to the principles involved in the economical use of steam. This part of the book is particularly lucid and concise, being perfectly clear to the average student. He also describes well the compound, triple, and quadruple expansion engines, especially dealing with the general idea of the expansion and course of the steam through the cylinders on its way to the condenser, as well as with the general laws regulating the volumes of the cylinders. Although the subject is treated in an elementary manner, there is much sound work in the book. Text-books on steam have greatly improved of late years from an engineer's point of view, and the present volume is a good example of the way in which the subject should be handled for the benefit of budding engineers.

The illustrations and diagrams are good, the former being taken from engines in actual practice. Fig. 134, however, does not represent particularly good practice. The flat crown of the fire-box of locomotive type of marine boilers is probably seldom stayed after the manner shown; the crown stays being generally screwed through the shell of the boiler, and either rivetted over or fastened with a nut and a copper washer. Assuming that these stays are screwed through the fire-box crown sheet, it would be interesting to know how the author proposes to place them in position, as shown in the figure. Fig. 137 represents a Ramsbottom locomotive safety valve. Although correct in principle, it is quite a curiosity in point of design, the valve in general use being very different in appearance, as the reader may observe by referring to the one shown on the locomotive boiler illustrated in Fig. 132. We may say in conclusion that a fuller index would have added considerably to the value of the book. N. J. L.

Australia Twice Traversed. By Ernest Giles. In Two Vols. (London: Sampson Low and Co., 1889.)

THE narrative presented in these volumes has been compiled by Mr. Giles from the journals written by him during five exploring expeditions into and through central South Australia and Western Australia from 1872 to 1876. The materials of the book are not, therefore, very fresh, but this ought not to detract much from their interest, as hitherto only fragmentary accounts of Mr. Giles's travels have been printed. It must be admitted that records of wanderings in the interior of Australia are not usually very fascinating. Mr. Lumholtz's book, which we lately reviewed, is a brilliant exception to the general rule. We cannot say that Mr. Giles's work rises to an equal height above the ordinary level; for it lacks that fine insight into

native life and temperament which is the special and most valuable characteristic of the Danish explorer's record. Moreover, Mr. Giles had to pass through much desert country, the description of which could have been invested with charm only by a writer of genius. The book, however, shows that he has the courage, resource, and spirit of enterprise which are absolutely essential to an explorer, and here and there his story is lighted up by what he has to say about the few well-watered and pleasant tracts of land through which he passed during his various journeys. His explorations were necessary links in the chain of Australian geographical research, and he has acted wisely in preparing a full and accurate account of them. The value of the work is considerably increased by maps and illustrations.

New Zealand for the Emigrant, Invalid, and Tourist. By John Murray Moore, M.D. (London: Sampson Low and Co., 1890.)

DR. MOORE spent nine years in New Zealand, and not only enjoyed his stay, but derived from it renewed health and vigour. When, therefore, he began to set down the results of his observation and experience, he was in the right mood for the production of a genial and appreciative record; and his book ought to be of considerable service to each of the three classes mentioned on the title-page. The most original parts of the work are two chapters, in one of which he indicates the various climatic zones into which New Zealand as a health-resort is divisible, while in the other he presents a full account of the characters and therapeutic achievements of the principal thermal springs of the North Island. Both of these chapters will be read with interest by medical men, and by invalids who may feel disposed, as the author puts it in the rhetorical style he sometimes affects, to "fly on the wings of steam to the realm of the Southern Cross." He gives a good description of Auckland, "the Naples of New Zealand," and sets forth pleasantly and effectively the impressions produced upon him during excursions to the hot lakes and terraces, and to the west coast Sounds. An instructive chapter is devoted to the volcanic eruption of Mount Tarawera, and Dr. Moore offers much valuable information about self-government in New Zealand, and the settlement of the land; and about social life, public works and institutions, productions and industries. The volume includes several maps, in one of which are shown New Zealand's climatic zones.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

A Key to the Royal Society Catalogue.

IN his anniversary address to the Royal Society, the President, referring to the great catalogue of scientific papers, used these words:—"The utility of the work would obviously be much increased if it could be furnished with some sort of key, enabling persons to find what had been written on particular subjects. I am not without hopes that this very desirable object may yet be accomplished, notwithstanding the magnitude of any such undertaking." Almost everyone engaged in scientific research must have felt the want of such a key, and will join in the President's hopes. My present object is to suggest a scheme for supplying the want at comparatively little trouble and expense.

A complete subject index, arranged in alphabetical order, would indeed be a great undertaking. The subdivisions being minute, most of the papers would have to be catalogued more than once, and, even if the references were only to the name of the author and the number of the paper in the present catalogue, the new catalogue would probably be as large as the old. The key that I suggest would be much smaller, and yet in many cases more convenient. The proposal can hardly be novel, but its advantages may not have been fully realized. Divide up the whole of science into some 5000 heads, classified in their natural order under the various branches—pure mathematics, astronomy, physics, chemistry, &c. Under each head place the names of the writers who have treated of the subject, with the dates of their earliest and latest papers thereon. If the heads are skilfully selected it will seldom be necessary to classify a paper under more than one head.

Some idea of the size of the suggested work may be gained from the following considerations. In the eight volumes of the catalogue at present published (1800–63 and 1863–73) are the names of about 57,000 authors, treating the names in the second part as entirely new. Of these, about 30,000 have only one paper each, and the remaining 27,000 average about eight papers each. In view of the tendency of all writers to devote themselves to special subjects, three heads seem a fair allowance for the papers of each of the 27,000 authors. We have thus 111,000 authors' names to be catalogued under 5000 heads, giving an average of about 22 names to each head. Such a list, printed in the style of the present catalogue, but with three columns instead of two in a page, would fill a volume of about 800 pages. Each of the present volumes contains about 1000 pages, and is sold at 20*s*., which we are told covers the cost of the paper and printing. If the sections devoted to the various sciences—chemistry, geology, &c.—were published separately, the sale would probably be large.

With regard to the use of this list, the labour of looking up 20 or even 50 names in the main catalogue would generally be trifling compared with the unavoidable labour of reading the actual papers when the references had been found. In many cases the dates would show at once that certain authors need not be referred to. Even if we had a complete alphabetical subject index, it would be necessary to think of every possible word by which the particular subject in question might be denoted, so that the classified list, though more troublesome at first, would often prove more satisfactory in the end. With 5000 heads for the whole of science, perhaps 750 might be allotted to physics, and of these, 150 to light. This would admit of such subdivisions as velocity of light, colour sensation, fluorescence, selective reflection, magnetic rotation of the plane of polarization, &c. Those subdivisions should be selected, into which the actual papers most naturally fall, rather than those which seem ideally correct.

The labour of preparing such a list as I propose would be in itself considerable, but, compared with the colossal enterprise which the Royal Society has already carried out, it would be small, and the service to science would be great.

Hotel Buol, Davos. JAMES C. MCCONNEL.

Osteolepidæ.

THE letter of your correspondent "R. L. + E." somewhat misses the issue raised in the passage to which he refers. In that passage the question was not raised whether or no we are right in making family names from the inflected form of the generic ones, the sole contention being for uniformity in this respect. Thus, if we are right in making *Rhizodontidæ* (and not *Rhizodidæ*) from *Rhizodus*, we clearly ought to have *Osteolepididæ* (and not *Osteolepidæ*) from *Osteolepis*, both these generic names being precisely analogous compounds. If, on the other hand, your correspondent is right in saying that we should regard all such names as adjectival, then we ought at once to abolish family names like *Macropodidæ*, *Dasypodidæ*, *Octodontidæ*, &c., in favour of *Macropidæ*, *Dasypidæ*, and *Octodidæ*. R. L.

THERE can be no question that "R. L. + E." is himself mistaken in his arbitrary assumption of a rule for the formation of compound adjectives in Greek. Sometimes the lengthened genitive is used as the stem, as in διαώματος ("disomatus"); sometimes the short nominative stem is employed, as in δίστομος ("distomus"); and sometimes both forms occur side by side, as φιλαίματος ("philæmatus") and φίλαιμος ("philæmus"), the former seeming to be preferred. These are words actually in use in Greek writers, and any lexicon will give plenty of other instances. But his whole argument is beside the point; the question is not whether an adjective is formed from the lengthened genitive, but whether an adjective, formed from a noun

which lengthens its genitive, lengthens its own genitive. It does so in every instance; *e.g.* we have *καλλίθριξ* with genitive *καλλίτριχος*, *μικροπτέρυξ* with genitive *μικροπτέρυγος*. Hence, in the Lepidoptera, we rightly call the family, of which *Micropteryx* is the type, the *Micropterygidæ*.

Osteolepis, though not occurring in Greek writers, is not "of questionable form," but as good a word as *φιλόπολις* and *φιλόπατρις*; and just as the latter actually forms a genitive *φιλοπάτριδος*, so also *ὀστεόλεπις* would form *ὀστεολέπιδος*, and the family name would be *Osteolepididæ*. Finally, it is to be remembered that the family name is not formed from a "possible" generic name, but from an existing one; so that *Ostiolepus* is out of the question, and indeed is only "possible" because there happens to be a word *λέπος* from which it can be derived.

I must apologize for troubling you at this length, but my fellow-workers in science are not unfrequently so hazy on the subject of classical nomenclature that there is a need for the setting forth of sound doctrine. E. MEYRICK.

The College, Marlborough, January 25.

AS to the facts of word-formation in Greek, Mr. Meyrick is, as was indeed to be expected, quite right, and might have put the case even more strongly. The short forms, like *πολύστομος*, are much rarer than those in which the full stem is found, like *πολυσώματος*. They are, indeed, unless I mistake, found only with the neuter stems in *-ατ-*, as in *δερμα(τ-)*, *στομα(τ-)*, *σωμα(τ-)*, *ἁιμα(τ-)*, *σπερμα(τ-)*, and appear to be a speciality of that class of nouns, where they occur beside, but not to the exclusion of, the full normal forms. There is no ground for thinking that a derivative form in *-lepos* could be formed from the noun *λεπις*, *λεπιδ-*, or a derivative in *-ornos* from *ὀρνις*, *ορνῖθ-*. **Osteolepus* and its alleged pl. **Osteolepi*, may certainly be pronounced impossible on Greek analogies; and could not even be grounded on the by-form of the noun, *λέπος*, stem *λεπε(σ)-*, since the adjective from that *-ος*, *-ες* stem, would necessarily end in *-λεπης*, *-λεπες*. As, therefore, *Osteolepid-* is the stem of the noun, the name of the family, on Greek analogies, is necessarily *Osteolepid-idæ*.

But I do not myself think that it is *always* necessary to conform to Greek analogies; I think that the convenience of English needs is also to be considered. In *Osteo'lepis*, *Osteo'lepi'didæ*, I think English needs are fairly answered; but it is not always so; some formations of the kind are hardly pronounceable, or when pronounced, through shifting of accent, presence of mute letters, pronunciation of *c*, *sc*, as *s*, and the like, do not in the least suggest their meaning.

Indeed, I think it very desirable that the Linnean and other learned Societies should establish a Committee of Nomenclature, who should consider every new name proposed, and pass or reject it, after taking into consideration not merely etymological correctness of formation, but what I think far more important, capability of being pronounced, distinctness from other existing names, and fitness for yielding derivatives, if needed. I entirely disagree with the notion that every discoverer of a genus has a right to confer a *name* upon it which he himself has never considered how to pronounce. I have had occasion repeatedly to ask inventors of such names, how they pronounced them, and have more than once been told that they had never thought of that, only of getting the Greek form right, and that I, forsooth, must settle the pronunciation! Such men were, of course, utterly unfit to confer names, however eminent as scientists. Every name that does not lend itself to a distinct and easy pronunciation, or which, when pronounced, is undistinguishable from some other word spelt quite differently (*e.g.* words in *cœno-*, *cæno-*, *sceno-*, *seno-*, &c.), ought to be rejected. Better invent new words off at the ground, having *no etymology*, than put together Greek roots in combinations unsuitable for modern mouths and modern ears. Why must modern knowledge be confined within the swaddling-bands of a nomenclature 2000 years younger? J. A. H. MURRAY.

Oxford, January 28.

Compounds of Selenium.

IN your issue of the 23rd ult. (p. 284) you insert a paragraph describing experiments by M. Chabrié on compounds of selenium. While fully acknowledging the value of his work on the phenyl derivatives of selenium, I think it right to state that much of M. Chabrié's investigation has been anticipated by Mr. F. P. Evans and myself as long ago as 1884; and that several of his assertions are incomplete and incorrect. The tetrachloride, $SeCl_4$, as we then showed, exists in vapour as such between 180° and 200°; with rise of temperature it dissociates, but even at 360°, dissociation is incomplete. In our paper (*Trans. Chem. Soc.*, 45, 62) the progress of the dissociation is followed.

We do not agree with M. Chabrié's suggestion that the products of dissociation are the other chloride, Se_2Cl_2, and chlorine, for the very good reason that Se_2Cl_2 itself is an extremely unstable body. Instead of, as he asserts, having a constant boiling-point at 360°, it begins to boil at 145°; and temperature rises to 173°, while a mixture of Se_2Cl_2 and $SeCl_4$ distils over, leaving a residue of selenium. The vapour-density of Se_2Cl_2 was found by us apparently normal; but this is caused in reality by the fact that it also dissociates completely on vaporization into selenium and chlorine without change of volume, according to the equation $Se_2Cl_2 = Se_2 + Cl_2$.

A revision of the experimental work of previous investigators is obviously to be desired; but it should be undertaken as a revision, else inaccurate conclusions may be drawn from incomplete work, as they have been in this case.

Perhaps I may be allowed to take this opportunity of inquiring by what reaction selenophenol, C_6H_5SeH, is produced from the red oil, $Se_2(C_6H_5)_2C_6H_4Cl$, out of which it is said to deposit on standing? WILLIAM RAMSAY.

University College, Gower Street, February 3.

Royal Victoria Hall and Morley Memorial College.

I HAVE only just read the article on Polytechnics for London in your number for January 16 (p. 242). I hope it is not too late to offer a few words of comment on it. Nothing is said of that part of the Commissioners' scheme which applies to the Royal Victoria Hall and Morley Memorial College, probably because the amount intended for them is comparatively small—£6000 down for structural alterations, and £1000 a year to be divided between Hall and College. But it derives an importance beyond what is due to the amount of the grant, from the fact that it is no castle in the air, but a going concern, and had begun its useful life long before the Commissioners had planned their scheme. Moreover, many of your strictures do not apply to this particular part of it. You say there will be, under the new scheme, "no People's Palaces—only *Young* People's Institutes." You object to limitation of age, and to smoking being forbidden, and you conclude by urging most truly that "life should come first, then buildings," for life develops from within.

May I therefore, in as few words as possible, give an account of the history and present position of the Hall and College, with the object of showing that the truths you urge have been already laid to heart?

The Hall (formerly the "Old Vic." Theatre) was opened 9 years ago as a temperance music hall, to compete with the degrading attractions of ordinary music halls, about which there was less stir in those days than now. At first we had variety entertainments every night, but before long the experiment was tried of introducing something better on certain nights. There is no need to enter into the ups and downs through which experience was gained; suffice it to say that we still have "variety" pure and simple on Saturdays, when our gallery boys, as well as well as their elders, enjoy themselves to their hearts' content, to the number of 1800 or so; and a modification of this kind of entertainment takes place before a much smaller audience on Mondays and Wednesdays. But on Tuesdays (as your readers know from the occasional notes which appear in your paper) we have popular illustrated lectures from many of our leading scientific men, who continually express their gratification at the appreciative attention of the audience. On Thursdays we have ballad and operatic concerts, at which (interspersed among operatic selections) tableaux, representing scenes from operas, are given. And on Fridays there are temperance entertainments.

All this will be left unchanged by the new scheme; and is not this something very like a "Palace of Delight"? Smoking is and will be freely carried on (except in certain parts of the house on concert nights), and anyone, without distinction of age, can come in by payments ranging from twopence on Thursdays and Saturdays, and from a penny other nights.

But this is not all. A little more than four years ago, classes were started in the unused dressing-rooms at the back of the stage, in response to a demand for more systematic instruction from some of those who had attended the lectures. The first

class began with four students, but soon the number was as great as the rooms could conveniently accommodate, and excellent work was done in spite of many inconveniences, one of the greatest of which was the impossibility of excluding the sounds of the entertainments in the Hall. From time to time *soirées* were held, and the students informally consulted as to what additional classes they wished for. Where a demand existed, every effort was made to obtain the supply.

Then came the offer of the Commissioners to meet a subscription with an equivalent endowment, and the freehold was bought, in memory of one of the truest friends of the work, Mr. Samuel Morley. Finally, the waste space which had been occupied by dressing-rooms and stores of old scenery was cleared of its dangerous wooden staircases, a sound-proof, fire-proof wall was built to divide it from the theatre, and large convenient class-rooms were built; and on the last day of September the Morley Memorial College was opened, for working men and women; Miss Goold (the well-known head of the Queen Square College) having consented to take the office of Principal here also.

Already there are 680 students on the books. Many criticisms may be made on the arrangements, but no one can say that there is a want of life in the place. The builder's men are hardly yet out of it, and the fittings are at present of the scantiest (the result of want of funds, for the delay in passing the Commissioners' scheme through Parliament has caused unlooked-for and very embarrassing delay in the receipt of the help expected from that quarter) but the enclosed prospectus will show ample signs of life. Admission to the gymnasium, smoking, and recreation rooms can only be gained by *bonâ fide* attendance on at least one class, a rule which the Committee consider very important, and which they adopted in consequence of their experience with a club which met at one time in some of the old rooms belonging to the Hall. No new students are admitted under 17, for the simple reasons that it does not answer to mix boys and men, and that the boys are provided for by the Recreative Evening Schools Association; but there is no limit of age at the other end. When the Borough Road Polytechnic is started, the College will probably take those students who want advanced literary and scientific teaching, excluding "technological classes," for which neither space nor funds would suffice. In fact, the College will be in all probability the advanced branch of the Polytechnic. At all events, it is intended that the two institutions should play into each other's hands and avoid overlapping.

You say most truly that life develops from within. I would go further, and say that "*omne vivum ex vivo*" is as true of moral and social as it is of organic life. No institution can grow and flourish unless life has been given in its service, and this is emphatically the case with that of which we are speaking. To mention names would not interest outsiders, and to those who have watched the Hall from its very beginning, nine years ago, it is well known whose heart work as well as head work has been devoted to it and kept it alive through its troubled infancy. This it is which has drawn other workers to help in doing what one alone could never accomplish, and given spirit to the whole. They have allowed life to develop from within, watching for what was practicable instead of airing preconceived theories, and this is why so little has had to be done twice over. Help of all kinds is greatly needed, for the concern is only in its early childhood yet, but one thing is certain—whatever wants have to be supplied and defects remedied, this is *not* an "architectural white elephant." Probably that could never be true of any institution which had so much heart as well as head devoted to it, but let those who doubt come and see for themselves!

February 5. A MEMBER OF COMMITTEE.

Galls.

IN NATURE of November 28, 1889 (p. 80), Prof. G. J. Romanes speaks of galls as "unequivocal evidence of a structure occurring in one species for the exclusive benefit of another," and states that "it is obvious that natural selection cannot operate upon the plants directly." Nevertheless, there is one way in which galls may be supposed to have been evolved as beneficial—or rather, less harmful—to the plants. Every farmer is aware of the great loss to vegetation caused annually by larvæ of insects boring within the branches and twigs of trees. Now suppose that all internal plant feeders were originally borers or leaf-miners—and this is highly probable,—but that some had a tendency to cause swellings in which they fed. These latter would be less injurious to the plants, and the greater the vitality of the plants the more nourishment for them; and so by degrees the globular and other highly specialized and least harmful galls would be developed, by natural selection, for the benefit not only of the insect, but also of the plant. And known galls, which I need not here enumerate, furnish us with all the steps of this evolution. T. D. A. COCKERELL.

West Cliff, Colorado, U.S.A., January 23.

Foreign Substances attached to Crabs.

THE Compound Ascidian referred to by Dr. R. v. Lendenfeld in yesterday's NATURE (p. 317) is one of the Polyclinidæ, and probably a new species. It belongs to the genus *Atopogaster*, and is closely related to *A. informis* (*Challenger* Report, Part ii. p. 171).

I have before me now five good specimens of the crab and Ascidian (the crab in this case is *Dromia excavata*, Haswell), dredged in Port Jackson, and sent by the Australian Museum, Sydney; they measure as follows:—

Specimen.	Crab (greatest diameter). cm.	Ascidian (length, breadth, and height). cm. cm. cm.
A	4	10 × 8 × 5
B	3·5	10 × 6 × 5
C	2·5	8 × 6 × 5.5
D	2·5	6 × 6 × 5
E	2·5	5·5 × 4·5 × 3

In the largest of them the Ascidian seems to be quite twenty times the size of the crab.

I notice in these specimens that the last pair of thoracic legs in the crab, which are much larger than the preceding pair, are turned up dorsally, and are so firmly embedded and attached by their sharp claws in the test of the Ascidian that it is easier to disarticulate them than to loosen their hold.

To those who dredge much round our coasts, a crab covered with foreign substances is no unusual sight. Specimens of *Hyas* are often found so overgrown with Algæ, Sponges, Zoophytes, and Polyzoa that almost the whole of the body and legs is hidden, and the animal is scarcely recognizable except by its movements. W. A. HERDMAN.

Liverpool, February 7.

The Ten and Tenth Notation.

IT is no doubt difficult for anyone to really conceive enormously great or infinitely small quantities. This difficulty is, however, much minimized by the ten and tenth notation. Indeed, if systematically used, I believe one's mental power of estimation would be practically perfect. But is it so used? I have before me three books—I only take this as an example of what frequently occurs—in which Joule's equivalent is given is—

$$\left.\begin{array}{l} 42 \times 10^6 \\ 4{\cdot}2 \times 10^7 \\ 0{\cdot}42 \times 10^8 \end{array}\right\} \text{respectively.}$$

B. A. MUIRHEAD.

Pall Mall Club, Waterloo Place, S.W., February 8.

P.S.—The natural uniform notation, at any rate for text-books, seems obvious.

EARTH TREMORS FROM TRAINS.

AMONG the writings of those who love to speculate on the future of our planet there is probably somewhere (though we have not had time to discover it) an essay on the cosmical changes which man will be able to produce in the earth. The data for solving this problem are striking. In a few centuries man has acquired all those powers over large and solid objects represented by his knowledge of explosives, and his use of steam. Multiply the centuries, and with them the history, by convenient figures (a familiar process in this kind of problem) and there is no reason why the earth's axis of rotation should not be shifted considerably by human agency.

For the present, however, we are concerned with a more

modest inquiry—to wit, how far the railways which jar the nerves of Mr. Ruskin so terribly, are desirable neighbours for anyone who prefers the earth under his feet to be firm and steady, as it was aforetime, and as it is now sometimes in remote parts of the country on Sundays. We have all noticed, when standing near a passing train, the vibration of the ground under our feet. Though this vibration decreases as we recede from the train, and may at a distance of 50 or 100 yards become insensible to such a coarse test as the actual jarring of our body, we can understand that it may be sufficient to disturb delicate instruments at a considerable distance; and thus affect the use of instruments requiring a steady foundation. Pre-eminent among such are astronomical instruments, and it was very early in the history of railways that astronomers found themselves compelled to fight for the retention of that steadiness of ground in their neighbourhood which is of vital importance to them, and with which no human agency had previously suggested an interference. It was in 1835 that the question of taking a railway near an Observatory was first raised, in connection with the Royal Observatory, Greenwich; and an animated discussion resulted in the defeat of the railway company.

But they have several times since returned to the charge, for Greenwich has always been an attractive centre for excursions, and there are many reasons why railway companies find it continually cropping up in their schemes; indeed, it is only a few months ago that the latest application of the kind was refused by Parliament.

On June 19, 1835, the Secretary of the Admiralty wrote to the Astronomer-Royal, Mr. Pond, asking for his comments on the proposed scheme for a Greenwich-Gravesend railway, passing in a tunnel under a part of Greenwich Park, in which the Royal Observatory is situated. Mr. Pond replied that he had no experience in such matters; but "the most important observations made at the Royal Observatory are those in which the stars are seen by reflection from a horizontal surface of mercury. It appears to me highly probable, by what I have experienced from slighter causes, that the passage of heavy carriages, even at the distance of the intended tunnel, might produce sufficient tremor on this surface to destroy the accuracy of these observations." On receiving this reply, Captain Beaufort, then Hydrographer to the Admiralty, wrote to a friend, Commander Denham, asking him to make experiments near one of the few existing lines of railroad—that between Liverpool and Manchester—with a sextant and artificial horizon. After explaining the object of the experiments, he says:—"It would be childish to be guided by opinions and suggestions, when the facts can be distinctly ascertained by means of the Liverpool and Manchester Railroad, and I therefore want you to take your artificial mercury horizon to that railroad, and watch the contact of a star or the sun in altitude with a telescope when the train is passing, at two or three different distances, till you come to the outer limit of vibration, or, in other words, to the distance at which the mercury is no longer affected. After you have tried this on the surface, I wish you would then try the same experiment in the neighbourhood of the tunnel, as I presume that the results will be very different."

Commander Denham's reply is as follows:—"I find the vibration of trains of 120 tons, at a speed of 25 miles an hour, affect the mercury as far as 942 feet laterally with the rails, on the same level, and on equal substratum; but vibration perfectly ceases at 1110 feet, whilst directly over the tunnel no vibration is detectable at 95 feet distance, though quite discernible at 65 feet vertical distance. . . . I am indebted to the co-operative accommodation of the directors, who allowed trains of extra weight, and at extra speed, to pass down at night hours when the busy hum (of carting carriages and bustle) was completely suspended."

In the printed report of this correspondence the Hydrographer notes on this letter: "It is proper to remark on the above that Commander Denham's experiments depended on observations with a sextant, and that the limits of tremors in the mercury would be far more extensive if viewed by the high magnifying powers used with the mural circle."

We have quoted this case in detail not only because it was the first experiment of the kind, but because the accuracy of the results, as interpreted by the Hydrographer's note, has been confirmed by later experiments. This report was adverse to the railway company, who wished to approach within 650 feet of the Observatory; but they did not relinquish their scheme at once. They suggested various plans—of running trains at slow speeds, or stopping them altogether if the Royal Observatory signalled that an important observation was just going on, and so forth—all of which were open to the objection of looking too well on paper. Meanwhile Mr. Pond had been succeeded by Mr. (afterwards Sir George) Airy, who, in 1836 January, repeated Commander Denham's experiments in the Glebe Meadow, near the Greenwich Railway, but using a small telescope instead of a sextant. He found that "a disturbance in the clearness of the image (in mercury) was perceptible when the train was 1106 feet from the mercury, and the image was almost lost from the violence of the agitation when the train was about 700 feet from the mercury. When the train was 500 feet from the mercury it was impossible to know whether there ought to be any object visible at all."

The question was ultimately resolved into a decision upon the minimum distance from the Observatory at which a railway could be allowed; and under strong pressure, Sir George Airy was induced to define this distance as something over 700 feet; but the position to which the line was thus removed was found to bring it near other buildings, and the project was ultimately shelved. The Astronomer Royal's troubles were, however, only just commencing. In 1840 the London and Chatham Railway Company asked for leave to go through the Park; being promptly followed by a similar application from the South-Eastern Company; and he must needs repeat his experiments and protests.

His experiments in March 1846 near the Kensal Green tunnel showed that tremor was sensible in the compact clay of Kensal Green to a distance of 1700 feet, but that the tremor was very much diminished where the railway enters a tunnel. Dr. Robinson, of Armagh, made independent experiments on the Dublin and Kingstown Railway. He mounted a mural circle on an ash post driven deeply into the ground, at a distance of 1655 feet from the nearest point of the line; and found that the vibration of passing trains gradually shook the instrument away from any position in which it was clamped, so that an object would not remain bisected by the cross wires. His reflection observations were numerous, and he sums them up as follows: "On these facts it is, I presume, unnecessary to offer any comment, except the simple remark that they show clearly that, in a soil such as I have described, a train of no uncommon weight or velocity can produce, at an oblique distance of two miles, such disturbance as ought never to be tolerated in an Observatory."

Sir James South also made experiments, and concludes his report to the Admiralty thus:—"To the observations of *right ascension made by reflection*, the more immediate object of this communication, let me then entreat your Lordships' serious attention, convinced, as I am, that, did they stand *alone*, they would justify your Lordships in saying to *present* as well as to *future* railroad applicants, 'WITHIN THIS PARK STANDS THE ROYAL OBSERVATORY OF ENGLAND, AND WITHIN THIS PARK'S WALLS A RAILROAD SHALL NEVER COME.'" (The italics and capitals are as in the original.)

These strong protests had the desired effect for the time being, and it was not till 1853 that another attempt was made to bring a railway within the Park. This was by the South-Eastern Company, and being postponed for a year, was not heard of again. In 1863, however, the London, Chatham, and Dover Company proposed a line from Dulwich to Epsom passing within 700 feet of the Observatory; and the South London, Greenwich, and Woolwich Railway another passing within 600 feet. Sir George Airy was at first inclined to think that, if these railways were laid in tunnels, they might be permitted. But as facilities for making experiments had meantime increased with the multiplicity of lines, he renewed his investigations at the suggestion of the Hydrographer, and found that the protection of the tunnel was by no means established; and in other respects he had been if anything too lenient in assigning minimum distances. His conclusions from the experiments were:—

"I. It is indispensable that the railway pass through the Park in a covered tunnel.

"II. It is indispensable that its minimum distance from the transit circle of the Royal Observatory exceed 1000 feet."

The result of all these independent experiments seem to be that even with small instruments, such as a sextant or a small telescope, vibration is sensible at 1000 feet distance; and that though a tunnel may be a protection in some cases (we shall presently find reason to question this more seriously) the reasons are not sufficiently understood to enable us to predict the influence of individual tunnels. All the observations, except one of Dr. Robinson's, have reference to reflection observations; but it does not follow that these are the only observations disturbed, as is made abundantly clear by the single observation of Dr. Robinson's referred to, where the telescope was practically shaken to another position against the clamp. It is in reflection observations that the vibration is most easily discernible, but errors introduced into other observations are no less serious because they are not readily detected. Observation with mercury is a delicate test, but it is quite possible that we may very soon find even a more delicate test necessary. We are, for instance, only on the threshold of photographic experiments for which the most perfect steadiness is essential; and it is of the utmost importance to make sure that our large Observatories are so protected as to be available for such work as is gathering shape in the mists of the near future. If any mistake has been made in dealing with railway proposals, it has been that of being too lenient; firstly, from the desire to yield as far as possible in matters affecting public convenience; and, secondly, perhaps from not fully appreciating the remark of Captain Beaufort in 1835, that the results obtained with small instruments must be properly magnified for dealing with large ones. This point has been made clear by the last case we shall quote, also from the history of the Royal Observatory. Proposals for an adjacent railway were renewed, as we have said above, in 1888. It had been already noticed that the lines which had been permitted were not sufficiently remote to prevent disturbance, and accordingly experiments were now made with the transit circle itself instead of with a small instrument. An observer was stationed at the transit circle prepared for a nadir observation, and for an hour noted the times when the images were steady, when partially disturbed, and when so agitated as to prevent observation. These times were noted carefully by a standard clock to within a few seconds. Other observers were furnished with watches set to standard time, and travelling on the various lines of railway in the neighbourhood noted the exact times of stopping and starting of all trains, entries into tunnels, &c. The observations were made near midnight when other traffic was stopped. On the following day the independent records of the transit circle observer and the train observers were compared. These operations were repeated on five separate nights. The result of the series of observations may be gathered from the following extract from the Report of the Astronomer-Royal to the Board of Visitors, 1888 June 2:—

"It resulted from these experiments that trains on the Greenwich-Maze Hill Railway caused great disturbance during their passage, not only on the section between Greenwich and Maze Hill, the nearest point of which is 570 yards from the transit circle, but also on the line beyond Greenwich on the London side, and beyond Maze Hill on the Woolwich side. The distances of the Greenwich and Maze Hill Stations from the Observatory are about 970 and 670 yards respectively . . . The disturbance was very great during the passage between Greenwich and Maze Hill, the reflected image being invisible while the train was in the tunnel, at a minimum distance of 570 yards, and there was considerable disturbance during the passage of trains through the Blackheath-Charlton tunnel, at a distance of a mile, the reflected image becoming occasionally invisible."

It thus appears that the tunnels increased rather than diminished the disturbance; and that the minimum distance for insensible tremor had been considerably underestimated. But the interference with the work of the Observatory is not serious. By the vigorous action of Sir George Airy and his successor the national Observatory has been saved from the misfortunes which have befallen Paris and Berlin, where traffic has been allowed to make certain classes of observation impossible.

H. H. TURNER.

TITANOTHERIUM IN THE BRITISH MUSEUM.

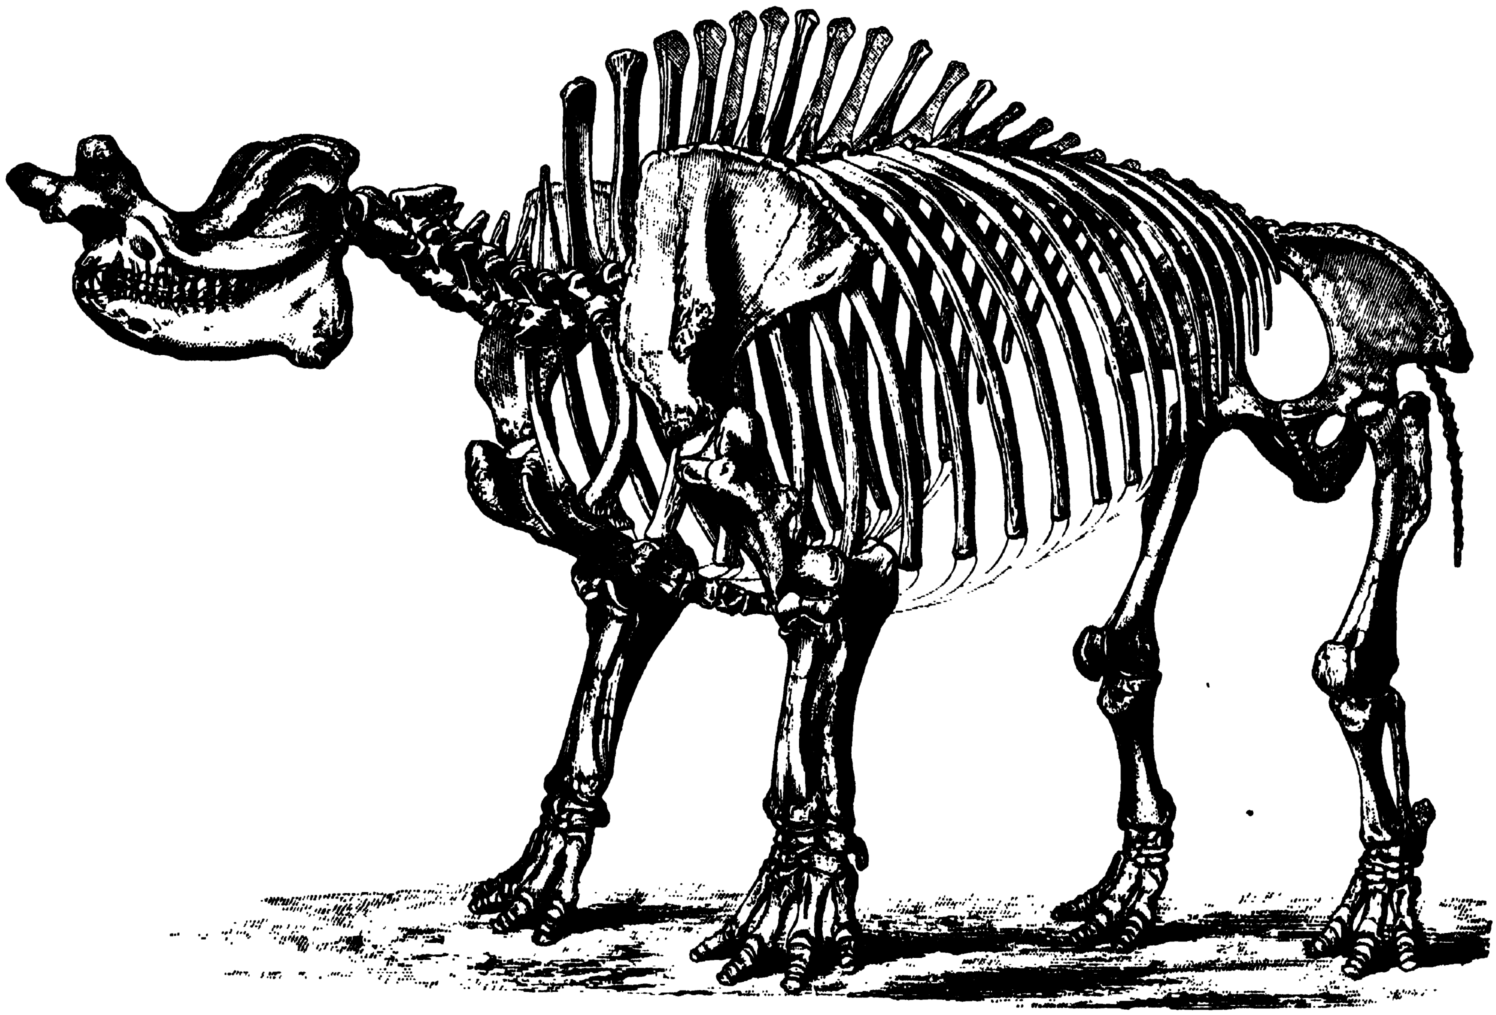
To those English zoologists who have not had the good fortune to visit the palæontological museums of the United States the huge Miocene mammals forming the family *Titanotheriidæ* have been hitherto known only by description and small-sized figures of the skull and skeleton, which, however excellent they may be, afford but a very inadequate idea of the proportions of these most remarkable Perissodactyle Ungulates. Recently, however, Prof. O. C. Marsh, of New Haven, to whose generosity our National Museum is already much indebted, has presented that institution with a beautifully executed model of the skull of one of these mighty brutes, which is now exhibited in the front palæontological gallery, below the head of the skeleton of the Kentucky mastodon. By singular good fortune the Keeper of the Geological Department of the Museum has been enabled at the same time to purchase associated examples of the teeth of another member of the family, which are placed alongside of the cast, and thus enable us to see the actual state of preservation in which the remains of these creatures are found.

The *Titanotheriidæ* were first made known to science from the evidence of specimens of the dentition described years ago by the French naturalist Pomel, by whom the name *Menodus* was proposed for their owner. Unluckily, however, this name was preoccupied by the earlier *Menodon*; and we are therefore compelled to adopt for the type member of the family the name *Titanotherium*, which is the first of the numerous terms proposed by American writers. The species of which the skull has been presented to the Museum is made by Prof. Marsh the type of a distinct genus under the name of *Brontops*. The chief distinction of this form from the type of *Brontotherium*, which seems inseparable from *Titanotherium*, appears to be the reduced number of incisors, but if writers like the Director of the Museum are right in regarding such variations in the allied group of the

Rhinoceroses as of not more than specific importance, this species should be included in the type genus.

These Titanotherioids appear to have been most nearly allied to the Rhinoceroses among existing forms, as is at once apparent from the contour of the skull. According to Prof. Marsh they were larger than the Dinocerata of the Eocene, and nearly equalled in size the existing elephants. The skull differs from those of the rhinoceroses, however, in that instead of having one or two horns placed in the middle line of the nasal region and having no sort of bony connection with the skull itself, it has two large processes of solid bone in a transverse line immediately over the nose, which were probably invested with a horny sheath.

The molar teeth are, moreover, unlike those of the rhinoceroses, having excessively low crowns, and an arrangement of the tubercles and ridges very similar to that obtaining in the Tertiary genera *Limnohyus* and *Chalicotherium*; the first of which is certainly, and the latter probably, a Perissodactyle, although the recent discovery that the peculiar claws upon the evidence of which the supposed Edentate genus *Macrotherium* was founded are referable to it, render it a most aberrant type.



Restoration of the skeleton of *Titanotherium robustum* ($\frac{1}{24}$ nat. size). After Marsh.

The skeleton to which the original of the cast presented to the Museum pertains was found in 1874 by the donor in those beds of the Dakota Miocene known as the Brontotherium beds, and it appears to be the best preserved example yet known. A restoration is given in the accompanying woodcut. According to Prof. Marsh these deposits are several hundred feet in thickness, and may be separated into horizons, characterized by peculiar species of *Titanotheriidæ*. The remains of several hundred individuals of this exclusively American group have already been secured by the palæontologists of New Haven, and their English *confrères* look forward to the publication of the sumptuous monograph in which Prof. Marsh promises to illustrate these specimens with much interest.

NOTES.

THERE is some talk of a Committee of the Royal Society being appointed to investigate the subject of colour-blindness, and the proper methods of testing the colour-vision of *employés* on railways.

WE may remind our readers that all applications for assignments from the Government Grant must be sent to the Assistant Secretary of the Royal Society on or before the last day of February. Applications received after that date will not be considered by the Committee of this year.

AN influential Committee has been formed for the purpose of securing that the scientific and other friends of the late Dr. McNab, Professor of Botany in the Royal College of Science, Dublin, shall have an opportunity of expressing their appreciation of his work and their respect for his memory. Through no fault of his own, Prof. McNab was unable to make adequate provision for his wife and five children; and it is proposed that the memorial shall consist of a fund, sufficiently large to be of real service to his family. A good many subscriptions have already been received or promised, and we hope that many more may be forthcoming. Mr. Greenwood Pim, Easton Lodge, Monkstown, Co. Dublin, acts as hon. secretary; Prof. W. N. Hartley, F.R.S., Royal College of Science, Dublin, as hon. treasurer. As Prof. Hartley has been obliged to leave Dublin for some time, all communications should be addressed, and cheques made payable, to the hon. secretary.

WE have already (p. 207) called attention to the fact that a committee has been formed in Paris for the purpose of making arrangements for the erection of a statue of the late M. Boussingault. His work marked an era in the history of the agricultural sciences, and we have no doubt there will be a prompt and liberal response to the committee's appeal for subscriptions. M. Pasteur is the honorary president of the committee. The acting president is M. Schlœsing, and the following are the vice-presidents: MM. Berthelot, Duchartre, Laussedat, Peligot, Risler, and Tisserand. MM. Müntz and Sagnier are the secretaries, and M. Liébaut is treasurer.

THE death of M. Sébastien Vidal, Director of the Botanic Garden at Manilla, is announced. He was well known for his researches on the flora of the Philippine Islands.

THE scheme of the Senate of the University of London, drawn up in accordance with the recommendations of the recent Royal Commission, does not at all commend itself to the authorities of the provincial Colleges. They are convinced that it would be most injurious to the interests of places of education outside the capital. This view was strongly expressed last autumn at a meeting of representatives of the provincial Colleges at Birmingham, and yesterday (Wednesday) it was pressed upon the attention of Lord Cranbrook by a deputation which waited upon him at the Privy Council Office.

TO-MORROW afternoon (Friday), at the Royal United Service Institution, Mr. H. Dent Gardner will read a paper on "The Ship's Chronometer—its History and Development." The paper will be divided into four parts: (1) historical, (2) historical-descriptive (the building up of the chronometer), (3) the chronometer of to-day, and (4) methods of testing and rating chronometers.

THE Ben Nevis Observatory Monthly Report for January is of more than usual interest. The rainfall during the month amounted to 29·42 inches, being 15·10 inches above the mean of the month since the Observatory was opened in 1883. A measurable quantity fell every day, and on 11 days over an inch was recorded each day, while on the 14th, 3·88 inches fell. The total bright sunshine amounted to only 4 hours, being the smallest number hitherto recorded. Lightning occurred on 5 days. The storm of the 5th was peculiarly severe, on which occasion the telegraph cable was damaged and communication stopped. St. Elmo's Fire was seen on the 21st and 25th, under the same relations to the cyclones then passing over North-Western Europe as described recently in NATURE.

WE have received from Mr. C. L. Wragge, Government Meteorologist of Queensland, his first Annual Report of the Meteorological Branch of the Post and Telegraph Department for the year 1887. It is divided into three sections. Section 1 gives an account of the organization, inspections, &c., containing a list of the recommendations originally made by Mr. Wragge, and a general statement as to how far each of them has been carried out. This synopsis shows that, while he has accomplished much during the year 1887, more still remains to be done. Section 2 contains abstracts of reports for each month from the rainfall stations, with climatological and other tables from the stations which are supplied with instruments. These abstracts contain very interesting data upon the state of the country, and will become more valuable in proportion as the number of verified instruments to be supplied year by year increases. As Mr. Wragge himself points out, any conclusions from so short a series of observations would be premature. Section 3 contains a graphic record of the chief meteorological elements for Brisbane, with seasonal wind charts and cloud charts for Queensland, and specimen wind charts for Australasia. These form the most interesting portion of the Report, and give promise of valuable materials for scientific study. In Western Australia, however, the weather charts show that there are vast tracts of country with apparently no meteorological stations.

THE last issue of the *Memoirs* of the Tashkent Observatory (Part 3) contains a most valuable magnetical map of part of Central Asia, based on the recent measurements of MM. Sharnhorst and Schwarz.

WE have already mentioned some of the conclusions as to the secular upheaval of the coasts of Finland which may be drawn from the accurate measurements made since 1858 under the direction of the Finska Vetenskaps-Societeten. We have now an elaborate paper on this subject, contributed by A. R. Bonsdorf to the *Izvestia* of the Russian Geographical Society (vol. xxv. 5). It appears from the mathematical analysis to which the measurements have been submitted that the average upheaval of the coasts of South-West Finland is 55 centimetres per century; and that the rate of upheaval increases from Ut-ö (in the Åland Islands) towards the north, and towards the east as far as Porkala (not far from Helsingfors), whence it decreases again towards the east. The interpolation formulæ better correspond to actual measurements if the changes of the level of the Baltic Sea resulting from the changes of atmospheric pressure are taken into account.

Globus reports that the Russian Geographical Society has presented a memorial to the Minister of Marine urging that scientific investigations of various kinds should be undertaken in connection with the Black Sea. Amongst other things, the Society points out that more exact soundings are needed in several parts of that sea, and that it is especially desirable they should be taken in the western part between Odessa and Constantinople.

ONE of the problems presented by the frightful eruption of Mount Bandai in Japan, two years ago, was the manner in which a large number of holes in the earth in the neighbourhood of the mountain were formed. It was suggested that they owed their existence to the falling of rocks and stones cast up the eruption, while another theory was that they were formed by forces beneath the surface. At the last meeting of the Seismological Society of Japan, Dr. Knott read a paper on the first theory, in which he demonstrated that it was quite insufficient to account for the phenomena. Prof. Milne, it may be added, has expressed the same view from the beginning.

LAST Friday a valuable paper on "The Utility of Forests and the Study of Forestry" was read before the Indian Section of the Society of Arts by Dr. W. Schlich, Professor of Forestry at the Royal College of Engineering, Cooper's Hill. In the course of his remarks Dr. Schlich gave an account of the instruction in forestry at Cooper's Hill, and mentioned that the authorities were thinking of appointing a second professor of the subject, and thus doubling the amount of instruction now given. After the reading of the paper Major-General Michael, C.S.I., who presided, made some interesting observations. No one, he said, who had visited the great forest regions of Germany, Austria, and France could fail to be impressed with the visible effects of good management, and to wish they were more generally apparent in England and Scotland. There were signs that the education and practical training of foresters were being more thought of at the present time in England, and he ventured to predict that Dr. Schlich would shortly have a good many students under him who were destined for home employment and not for India only. Personally he knew more about the value of forestry and the life of a forester in India, having spent seven or eight of the happiest and perhaps the most useful years of

his youth as a forest officer. That was more than 40 years ago, before the time arrived for experts like Dr. Schlich and his distinguished predecessor Sir Dietrich Brandis to come to the country. He could therefore tell any of Dr. Schlich's students who might be present that the life of a forester in India was not only a career of importance, but that it was one full of interest and of real enjoyment. The formation of the department in which they would serve had justly been characterized by Sir Richard Temple as one of the greatest achievements effected in India during the Queen's reign.

THE Royal Society of New South Wales offers its medal and a prize of £25 for the best commnication (provided it be of sufficient merit) containing the results of original research or observation upon each of the following subjects:—(To be sent in not later than May 1, 1890)—The influence of the Australian climate (general and local) in the development and modification of disease; on the silver ore deposits of New South Wales; on the occurrence of precious stones in New South Wales, with a description of the deposits in which they are found. (To be sent in not later than May 1, 1891)—The meteorology of Australia, New Zealand, and Tasmania; anatomy and life history of the Echidna and Platypus; the microscopic structure of Australian rocks. (To be sent in not later than May 1, 1892)—On the iron ore deposits of South Wales; on the effect which settlement in Australia has produced upon indigenous vegetation, especially the depasturing of sheep and cattle; on the coals and coal measures of Australasia. The competition is not confined to members of the Society, nor to residents in Australia.

M. LIGNIER has been appointed Professor of Botany to the Faculty of Sciences at Caen; and Mr. G. C. Druce, author of the "Flora of Oxfordshire," succeeds Dr. Schönland as Curator of the Fielding Herbarium at Oxford.

HERR JADIN, of Montpellier, has undertaken a voyage for the investigation of the algal flora of the islands Mauritius and Réunion; and Prof. P. L. Menyhardt, who has been appointed to a mission on the Zambesi, is intending to make a collection of plants in the region between the Zambesi and the sources of the Congo.

FOR the purpose of growing plants under more natural conditions than those usually afforded by the soil and surroundings of ordinary botanic gardens, M. G. Bonnier, the Director of the Botanic Garden in Paris, has obtained from the Director for Higher Education in Paris the grant of a piece of land in the Forest of Fontainebleau, as an annexe for experimental culture. It has been placed under the special charge of M. Cl. Duval.

AT the meeting of the Royal Botanic Society on Saturday a sweet-scented fern, from the Society's garden, was exhibited. The perfume, which closely resembles that of fresh hay, is retained after the frond is dry, and lasts for many months, if not years, imparting its fragrance to anything in contact with it. The secretary thought it might be grown as a source of perfume by amateurs, if not commercially. As yet it appeared to be little known in collections of exotic ferns. Some fine blooms of scarlet anemone, gathered from plants growing in the open air in Rutland, were shown by Mr. T. H. Burroughes.

IT is a good sign that the present building of the Bethnal Green Free Library has become quite inadequate for the needs of the institution, and that much larger premises are, if possible, to be erected. The sum of £20,000 is required, and many donations have already been received or promised. We may note that a largely attended meeting at the Bethnal Green Free Library lately started as tudents' union, for the study of various branches of science and art, in connection with the evening classes.

IN his "History of Barbados," published in 1848, Sir Richard Schomburgk says of the Barbados monkey that it was found in large numbers by the first settlers. From the appearance of a living specimen he considered it "to be *Cebus capucinus*, Geoff., the Sai or Weeper, or a very closely allied species." In the current number of the *Zoologist* Col. H. W. Feilden presents a wholly different view. He asserts that the Barbados monkey is an Old World form, the Green Monkey, *Cercopithecus callitrichus*, Is. Geoffr., and that its original habitat is West Africa. "This," he says, "undoubtedly proves its introduction to Barbados by the Guinea trading-ships." Col. Feilden cannot discover any warrant for Schomburgk's statement that this animal was found in large numbers by the first settlers on their arrival. The subject is interesting because of its bearing on the general view set forth by Col. Feilden, that Barbados has had no continental connection since the introduction of its present flora and fauna, but has received its terrestrial animals and plants from the effects of ocean currents, winds, accidental occurrences, or by the agency of man.

THE Council of the Ceylon Asiatic Society, in its last Report, urges on the Government the importance of systematically collecting, transcribing, and publishing the manuscripts of the ancient literature of the island which are scattered about in the libraries of temples, as well as in private houses. The researches which have already been made by individuals, or on behalf of the Government, show that manuscripts of great value may be found. During the last three years, private exertions have secured 69 of these; but what is needed is that the work should be undertaken as carefully and systematically as in India, where the duty of preserving the ancient literature of the country has been recognized by the Government, and where the collection of ancient manuscripts has for years past been conducted by a large staff of officers.

SUGAR seems to be losing its attractions for Lepidoptera. Mr. Joseph Anderson writes to the *Entomologist* from Chichester that his experience agrees with all that has been written on this subject lately. In the trees surrounding his house, and in those of his neighbour's garden, he has good sugaring grounds, and in former years they brought him a satisfactory return for the trouble expended on them, his captures numbering about fifty different species. "Now," he says, "for three or four years past, night after night, sugaring has been almost of no avail. Can it be a case of inherited instinct? And are the rising generation of moths getting too wise to be trapped by the sugaring baits?"

WITH the aid of an apparatus called a *periscope*, the submarine boat *Gymnote* was lately, it will be remembered, piloted safely in Toulon harbour. This enables the officer directing the movements to have a wide view around; and it consists of a vertical telescopic arrangement, with a lenticular total reflection prism at the top held between the tube and a cover above. After reflection in the prism, the rays converge at a certain point, and are received by a lens, the principal focus of which coincides with this point; thus a vertical cylindrical beam is formed, which meeting a mirror below, inclined at 45°, is directed horizontally to the eye-piece. A diaphragm, having a small radiating tongue, and moved by a tangent screw, enables one to intercept the view of the vertical plane in which the sun is, the tongue being brought to coincide with the plane. The system is said to work admirably.

EXPERIMENTING lately on the sense of smell, Dr. Zwardemaaker, of Utrecht, devised an olfactometer, which consists simply of a glass tube with upward curving part to be inserted in the nostril. A short movable cylinder made of some odoriferous substance fits over the outer straight end of the tube.

On inhaling, one perceives no odour so lon ; as this cylinder does not project beyond the inner tube ; but the further it is pushed out, the larger is the scented surface presented to the entering air, and the stronger the odour perceived. The author studies mixture of odours by applying a cylinder saturated with a scented body to the end of the olfactometer, and varying the length of the two odoriferous substances. But he considers a double olfactometer better (one tube for each nostril). With this, one may easily experience how one odour will overwhelm another ; rubber, *e.g.*, causing the smells of paraffin, wax, and tolu to disappear. Even with very strong excitants, there is never a mingling of sensations. Either the one or the other odour is perceived, till by careful equilibration of the two, no sensory effect at all is perceived. Sensibility is quite eliminated.

THE Verein für Erdkunde, of Halle, is arranging for a hydrographical and zoological investigation of the Lake of Ploen, in Holstein.

VIENNA and Berlin will shortly be connected by telephone.

A PRETTY and convenient celluloid paper knife is being sent by Messrs. Woodhouse and Rawson United, Limited, to their clients. No one who uses it can doubt that celluloid may for some purposes be a very good substitute for ivory.

MESSRS. WILLIAM WESLEY AND SON have issued No. 99 of their "Natural History and Scientific Book Circular." It consists of a list of works in astronomy, mathematics, and physics.

A PAPER upon phosphorus trifluoride is contributed by M. Moissan to the February number of the *Annales de Chimie et de Physique*. In a previous communication it was shown that this interesting gas could be obtained either by heating a mixture of lead fluoride and copper phosphide, or by the action of arsenic trifluoride upon phosphorus trichloride. Since that time it has been found that a regular and more rapid evolution of phosphorus trifluoride occurs when a mixture of zinc fluoride and phosphorus tribromide is gently warmed, and this appears to be by far the most convenient way of obtaining the gas in quantity. Zinc fluoride reacts much more rapidly than lead fluoride, and is best prepared by the action of pure hydrofluoric acid upon zinc carbonate. The insoluble fluoride thus obtained is washed with distilled water and dried at 200° C. It is important not to raise the temperature beyond this point, as further heating renders it much less easily attacked by phosphorus tribromide. The dry zinc fluoride is then placed in a brass tube closed at one end and fitted at the other with a double bored ordinary cork, well paraffined, and through which pass two tubes, one a delivery tube of lead, and the other a kind of dropping funnel, from which the tribromide of phosphorus is allowed to slowly fall upon the gently warmed fluoride of zinc. As soon as the temperature of the latter has begun to rise, the action becomes very energetic, and in a few moments several litres of the gas may be collected. In order to free the phosphorus trifluoride from admixed vapour of phosphorus tribromide, it is quite sufficient to allow it to bubble through a little water contained in a small wash bottle, after which it may be dried by passing through tubes containing pumice, which has been boiled in strong oil of vitriol, and heated until only the minimum quantity of sulphuric acid remains adhering to it, inasmuch as the strong acid absorbs a notable quantity of phosphorus trifluoride. The gas is finally collected over mercury. The reaction occurring during the preparation is stated to be as follows :—

$$3ZnF_2 + 2PBr_3 = 2PF_3 + 3ZnBr_2.$$

Gaseous trifluoride of phosphorus as thus prepared possesses a very sharp odour, but does not fume in the air. It is very slowly absorbed by water, but is decomposed immediately by solutions of chromic acid or potassium permanganate. As the above reaction appears to yield the gas in a very pure state, M. Moissan has made determinations of its density, and finds it to be 3·03. The calculated density of PF_3 is 3·08. When a measured quantity of the gas is heated over mercury in a closed glass vessel, it is totally decomposed by the silica of the glass, and the volume diminishes by one-fourth, four molecules of PF_3 becoming converted into three molecules of gaseous silicon tetrafluoride, SiF_4.

THE additions to the Zoological Society's Gardens during the past week include a Ring-tailed Lemur (*Lemur catta*) from Madagascar, presented by the executors of Dr. Allen ; a Vulpine Phalanger (*Phalangista vulpina* ♀) from Australia, presented by Mr. W. H. Seward ; a Hamster (*Cricetus frumentarius*) from Russia, presented by Mr. Harold Hanauer, F.Z.S. ; an Alligator (*Alligator mississippiensis*) from Florida, presented by Mr. A. B. Archer ; a Hoffmann's Sloth (*Cholopus hoffmanni*) from Panama, deposited.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on February 3 = 7h. 35m. 32s.

Remarks.

(1) The General Catalogue description of this nebula is as follows :—"Pretty bright ; considerably small ; round ; very gradually a very little brighter in the middle ; mottled as if with stars ; almost planetary." The spectrum of the nebula has not yet been recorded.

(2) Dunér describes the spectrum of this star as a very fine example of the Group II. type. He states that all the bands 2–8 are wide and dark, especially 2 and 3, and that the whole spectrum is well developed. No mention is made of the presence or absence of absorption lines, but there is little doubt that some will be found if looked for, the predominance of the bands 2 and 3 probably indicating that the star belongs to a later species, and is therefore approaching Group III., in which line absorption is predominant. Observations of the green and blue carbon flutings are also suggested (see p. 305).

(3) This star has hitherto been described as having a spectrum of the solar type. The usual observations, as to whether the temperature of the star is increasing (Group III.) or decreasing (Group VI.) are required.

(4) Gothard classes Procyon with stars of Group IV., but the Henry Draper Memorial photograph of the spectrum seems to indicate that it would be more properly described as an early stage of Group V., differing from the solar spectrum in having the hydrogen lines more developed and the metallic lines slightly thinner. Further observations of the visible spectrum are suggested.

(5) According to Dunér the spectrum of this star belongs to Group VI., and shows the usual three absorption bands of carbon. Band 6, which appears to be the most variable, is stated in this case to be very dark, and the question is, Are there any other variations in the spectrum accompanying the condition in which band 6 is dark? It seems probable that the number and intensities of the secondary bands will be found to vary with band 6, and these should, therefore, receive special attention.

(6) This variable has a spectrum of the Group II. type, but Dunér does not give a complete description, as he probably did

not observe it at maximum. A further examination is therefore required. Bright lines should also be carefully looked for, in order to determine whether the appearance of bright lines at the maxima of stars of Group II. is general. The period is given by Gore as 256 days, and the range as from 7·5–8·5 at maximum to < 12·2 at minimum. The maximum will occur on February 24.

A. FOWLER.

SPECTRUM OF THE ZODIACAL LIGHT.—In this month's *Observatory*, Mr. Maxwell Hall gives the results of a series of observations of the zodiacal light made at Jamaica. The observations are divided into three groups, according to the angular distance from the sun of the part of the zodiacal light observed. With respect to the first group, made at a distance of 50° from the sun, it is noted that the spectrum was seen as a faint white continuous band, commencing suddenly at λ 561, and extending as far as G, where it died out very gradually. The limit was well determined by comparison with the carbon flutings at λλ 470, 517, and 564. The result of the second group of observations, made at a distance of 22° from the sun, showed that the spectrum commenced at λ 561, but not so suddenly; its feeble maximum was transferred to about λ 517; from thence it was tolerably uniform to about λ 497, and then it gradually diminished and faded away at G.

The observations made at a distance of 15° from the sun gave λ 562 for the limit of the red end of the spectrum, and G as before for the violet end. But the spectrum did not commence at all suddenly: the stronger maximum was still at λ 517: it was fairly uniform from thence to λ 497, and then faded away.

Observations of twilight are needed to determine whether, as it grows more and more faint, the maximum appears to shift towards the red end of the spectrum or not; if not, the change in intensity of portions of the spectrum of the zodiacal light as observations are made at varying distances from the sun are peculiar to it, and need further investigation.

SOLAR AND STELLAR MOTIONS.—Prof. J. R. Eastman, in his address as retiring President of the Philosophical Society of Washington, delivered December 7, 1889, gave an exhaustive account of the investigations that have been made to determine the co-ordinates of the solar apex and the annual value of the motion of the solar system. His investigations into the relation between stellar magnitudes, distances, and motions, show that, in opposition to the assumption generally accepted, which asserts that the largest stars are nearest the solar system, there is an almost uniformly *increasing* proper motion as the stars grow fainter. Forty-six stars, that is, practically all those whose parallaxes have been well determined, have been tabulated and arranged in five nearly equal groups according to the magnitude of their proper motion. The following table gives the mean results found for each of the groups:—

	Number of Stars in Group.	Mean Magnitude.	Mean Proper Motion.	Mean Parallax.
			″	″
1st Group	9	5·57	4·93	0·32
2nd ,,	9	5·59	2·33	0·20
3rd ,,	9	3·37	1·04	0·20
4th ,,	9	2·36	0·38	0·16
5th ,,	10	2·84	0·06	0·13

The mean magnitude of the first two groups is 5·58, and the mean proper motion is 3″·63. Of the last three groups the mean magnitude is 2·86, and the mean proper motion is 0″·49.

If the 46 stars investigated be arranged according to the magnitude of their parallaxes, it is found that 18 of them have a parallax greater than 0″·2. The mean magnitude of these stars is 5·56, and the mean parallax is 0″·34. Of the remaining 28 stars the mean magnitude is 2·89, and the mean parallax is 0″·11. From this it would appear that, if any law can be formulated from the observed data, it must be that the fainter rather than the brighter stars are nearest the solar system.

DUN ECHT OBSERVATORY.—The Earl of Crawford, in a circular issued on the 29th ult., expresses his thanks for the hearty co-operation he has met with at all hands in his endeavours to advance the science of astronomy. Although some little time will elapse before all the instruments can be removed from Dun Echt to the Royal Observatory at Edinburgh, the former observatory must be looked upon as closed, and the generous donor trusts that the astronomical friends who have for years continued to enrich the library at Dun Echt Observatory with donations of books and pamphlets will extend their liberality to the new home of the collection at Edinburgh. The important astronomical work done by the Earl of Crawford personally, and at his observatory, has contributed, in no slight degree, to the progress of astronomy, and the very generous gift to the nation of the entire contents of the observatory at Dun Echt is worthy of the man, and appreciated by all friends of the science throughout the world.

MELBOURNE OBSERVATORY.—We have received from Mr. Ellery the volume containing the results of transit circle observations made from the beginning of 1881 to the end of August 1884. The separate results for R.A. and N.P.D. have been taken directly from the transit books, and also the observer's estimates of the magnitude. The places and magnitudes of the stars given in the annual catalogues have been derived from these separate results by taking their arithmetical mean.

GEOGRAPHICAL NOTES.

AT the meeting of the Royal Geographical Society on Monday, Mr. Douglas W. Freshfield read a most interesting paper on "Search and Travel in the Caucasus: an account of the discovery of the fate of the party lost in 1888." He began by acknowledging his obligations to M. de Stael, the Russian Ambassador to the Court of St. James's, the officials at Vladikavkaz, and more particularly to MM. Jukoff and Bogdanoff, of the Russian Survey, for the facilities and assistance given to him and his companions in carrying out the object of his journey. The topographical information accumulated by the surveyors had been placed at his disposal with the greatest readiness, and part of the result might be seen in the great map (6 inches to the mile) of the central group hung on the wall. The heights of the principal peaks were now ascertained. There were eight higher than Mont Blanc, and fifteen of over 15,000 feet. The four highest are Elbruz, Koshtantau, Shkara, and Dychtau. Ushba is 15,600 feet. Mr. Freshfield briefly described the new carriage pass, the Mamison, 9400 feet, from Vladikavkaz to Kutais. Its scenery is finer than that of the Dariel, and the road has been well engineered, but it will shortly fall into ruin unless a service is organized for its maintenance. He referred to the remarkable old Ossete sanctuary of Rekom, at the foot of the Ceja Glacier, and to the tombs found at Chegem, and exhibited a collection of metal and other objects discovered mostly at Styr Degir. In many villages small settlements of "Mountain Jews" were found. There were over 20,000 of this race in the Caucasus, and a work on them has lately been published at Moscow. The author, M. Mirimisoff, states that their beliefs and superstitions are singular, and show Persian influence, but they have had for centuries no connection with the rest of their race, from which they were probably separated at a very early date. The party had crossed five high glacier passes before reaching Suanetia. Here Mr. Freshfield and Captain Powell were the guests of Prince Atar Dadish Kilia, the representative of the family who once ruled Lower Suanetia. He now spends a few months in the summer at his house at Ereri, dispensing hospitality in feudal fashion among his retainers. The population assembles every Sunday for games on the green, and the women sing ballads recounting incidents in local history or tales of love and revenge. The Leila peaks (13,400 feet) south of Suanetia were ascended for the first time. They are pre-eminent in forests and flowers. One of the glaciers falls over a cliff in avalanches into a glen which is a bed of wild roses and yellow lilies, growing often with fourteen blooms on one stalk. From Suanetia to Sukhum Kaleh the travellers forced a way with mules through an almost trackless forest, and down the deserted valley of the Kodor, the region that was once Abchasia. Strange tales are told of the forest, even by Russian officials, who declared that a wild race, without villages, arms, or clothes, haunted its recesses. No one was met, however, but a few hunters and shepherds. But considerable difficulty was met with in forcing a way through the tangle of fallen timber and finding a passage over the torrents, and the native guides employed deserted the travellers before they reached Lata, the first Russian station on the Kodor. Mr. Freshfield proceeded to relate in detail the incidents of the search undertaken by Mr. C. Dent and himself, with the aid of Mr. H. Woolley and Captain Powell, for traces of the fate of the mountaineers, Mr. W. F. Donkin, Mr. H. Fox, and two Meiringen guides, lost in August 1888. It was known, from a note in a diary left by Mr. Fox in a lower

camp with his heavy luggage, that the lost party had set out from the Dumala Valley in the Bezingi District, with the hope of climbing Dychtau, 16,880 feet, from the south-east. Karaoul, at the head of the Cherek Valley, was made, therefore, the head-quarters of the search party. They bivouacked under a rock beside the Tutuin Glacier, at a height of 9400 feet. Next morning (July 29) they started at dawn, and forced, not without difficulty, a passage through the monstrous *séracs* of the Tutuin Glacier. Above them they found a long snowy corridor leading to the base of Dychtau, and to the foot of a gap in its east spur, which they believed Mr. Donkin and his companions had crossed from the Dumala glen on the further side. Nothing was found at the foot of the steep rock wall, 1400 feet high, which protected the pass. The searchers therefore climbed the rocks leading to it, and when 1000 feet above the snow and some 400 below the ridge, the traces sought were met with. The leader at the rope's end suddenly stopped short and gasped, "See, here is the sleeping-place." Before our eyes rose a low wall of loose stones built in a semicircle convex to the lower precipice. A crag partially overhung it; any object dropped over the wall fell 1000 feet on to the snow plain below. The space, some 6 feet square, inside the wall, was filled with uneven snow or ice, from which portions of knapsacks and sleeping bags protruded. A black stew-pan, half full of water, in which a metal cup floated, lay against the rock; a loaded revolver was hung beside it. It cost more than three hours' hard work to dig out all the objects from the frozen stuff in which they were embedded. Only three could work at once in the narrow space, and Mr. Freshfield and Mr. Woolley went on to the ridge, where they found a small stoneman, but no written record. Some manuscript notes and maps of Mr. Fox's were found in the bivouac, but nothing written after leaving the lower camp. The whole of the cliff and cliff's foot were carefully searched with a strong telescope. Mr. Woolley and his guides twice passed along the cliff's foot on his ascent of Dychtau, and he made certain that the party had not climbed the peak—that the accident therefore had happened on the ascent. After the lecture, Mr. Freshfield showed in the lantern a series of views of the Caucasus, from photographs by Mr. Hermann Woolley and Signor V. Sella. A complete set of Signor Sella's views, embracing eight panoramas and 90 views, was shown in an adjoining room. The panorama from Elbruz shows the whole chain of the Caucasus above a sea of clouds, and is probably the finest mountain photograph yet exhibited.

THE last issue of the *Isvestia* of the Russian Geographical Society is more than usually interesting, as it contains detailed letters received from the members of the three Russian expeditions now engaged in the exploration of Central Asia. The letter of M. Roborovsky, dated August 16, and written in the highlands to the south of Yarkend, contains a most vivid description of the journey from the town Prjevalsk to Yarkend, across the passes of Barskaun and Bedel. M. Roborovsky knows Central Asia well, as he was Prjevalsky's travelling companion during three of his great journeys; and his descriptions of the country—its orography, climate, and flora—are full of most valuable information. Another letter is from M. Bogdanovitch, the geologist of the expedition, who joined it at Yarkend, after having crossed the Kashgarian Mountains on another route and explored the Mustagh-ata glaciers. That part of the Pamir border-ridge had already been explored by Stoliczka, but M. Bogdanovitch adds much new information. It appears—as might have been expected from the orography of the region—that there is no trace of mountains running north and south on the eastern edge of the great Pamir plateau. The Kashgar Mountains are an upheaval of gneisses, metamorphic slates, and Tertiary deposits, running from north-west to south-east. The limestones which Stoliczka supposed to be Triassic, proved to be Devonian. The most characteristic fossils of the Upper Devonian (*Atrypa reticularis*, *A. latilinguis*, *A. aspera*, *Spirifer Verneuli*, and several others) were found together with the corals (*Lithodendron*), Stromatoporæ and *Cerioporæ* described by Stoliczka. The Tertiary sandstones are broken through (as is often the case in Siberia) by dolerites of volcanic origin; at the very border of the plateau, on its slope turned towards Kashgaria. Another series of letters, the last of which is dated September 23, from the sources of the Aksu, is from Colonel Grombchevsky. The late spring delayed the advance of the expedition, which spent the first part of June in crossing the Alai Mountains. The great Alai Valley of the Pamir could be reached only on June 19, but the Trans-Alai Mountains were buried in snow; no passage was possible, and the explorer was compelled to march to the lower tracts of Karategin. He thence proceeded to Kala-i-khum, a little town situated on the Pendj, at a height of 4500 feet, and enjoying a relatively mild climate. From Kala-i-khum M. Grombchevsky succeeded in reaching the Vantcha river; but having met there the Afghan troops which were taking possession of the khanates of Shugnan and Rothan, he could not move further south, nor explore the western parts of the Pamir; so he proposed to continue the exploration of the eastern parts of the Roof of the World. Finally, the two brothers, Grum-Grzimailo, who are exploring the Eastern Tian-Shan from Kuldja to Urumtsi, give short news of their progress, and remark that our maps of Eastern Tian-Shan are quite incorrect—a circumstance which might have been guessed from the general orographical structure of Central Asia. The collections of vertebrates and insects which have been gathered by the two explorers are exceedingly rich.

A PERMANENT Marocco museum is to be established at the head-quarters of the Society of Commercial Geography at Berlin.

SMOKELESS EXPLOSIVES.[1]

II.

SO far as smokelessness is concerned, no material can surpass *gun cotton* pure and simple; but, even if its rate of combustion in a firearm could be controlled with certainty and uniformity, although only used in very small charges, such as are required for military rifles, its application as a safe and reliable propulsive agent for military and naval use is attended by so many difficulties, that the non-success of the numerous attempts, made in the first twenty-five years of its existence, to apply it in this direction, is not surprising.

Soon after its discovery by Schönbein and Böttger in 1846, endeavours were made to apply gun-cotton wool, rammed into cases, as a charge for small arms, but with disastrous results. Subsequently von Lenk, who made the first practical approach to the regulation of the explosive power of gun-cotton, produced small-arm cartridges by superposing layers of gun-cotton threads, these being closely plaited round a core of wood. Von Lenk's system of regulating the rapidity of burning of gun-cotton, so as to suit it either for gradual or violent action, consists, in fact, in converting coarse or fine, loosely or tightly twisted, threads or rovings of finely carded cotton into the most explosive form of gun-cotton, and of arranging these threads or yarns in different ways so as to modify the mechanical condition, *i.e.* the compactness and extent and distribution of enclosed air-spaces, of the mass of gun-cotton composed of them. Thus, small-arm cartridges were composed, as already stated, of compact layers of tightly-plaited, fine gun-cotton thread; cannon cartridges were made up of coarse, loose gun-cotton yarn wound very compactly upon a core; charges for shells consisted of very loose cylindrical hollow plaits (like lamp wicks), along which fire flashed almost instantaneously; and mining charges were made in the form of a very tightly twisted rope with a hollow core. While the two latter forms of gun-cotton always burned with almost instantaneous rapidity in open air, and with highly destructive effects if they were strongly confined, the tightly wound or plaited masses burned slowly in air, and would frequently exert their explosive force so gradually when confined in a firearm as to produce good ballistic results without appreciably destructive effect upon the arm. Occasionally, however, in consequence of some slight unforeseen variation in the compactness of the material, or in the amount and disposition of the air-spaces in the mass, very violent action would be produced, showing that this system of regulating the explosive force of gun-cotton was quite unreliable.

Misled by the apparently promising nature of the earliest results which von Lenk obtained, the Austrian Government embarked, in 1862, upon a somewhat extensive application of von Lenk's gun-cotton to small arms, and provided several batteries of field guns for the use of this material. The abandonment of these measures for applying a smokeless explosive to military purposes soon followed upon the attainment of unsatisfactory results, and was hastened by the occurrence of a very destructive

[1] Friday Evening Discourse delivered by Sir Frederick Abel, F.R.S., at the Royal Institution of Great Britain, on January 31, 1890. Continued from p. 330.

explosion at gun-cotton stores at Simmering, near Vienna, in 1862.

It was at about this time that the attention of the English Government, and through them of the lecturer, was directed to the subject of gun-cotton, the Austrian Government having communicated details regarding improvements in its manufacture accomplished by von Lenk, and results obtained in the extended experiments which had been carried out on its application to the various purposes above indicated, according to the system devised by that officer. One of the results of the lecturer's researches, subsequently carried on at Woolwich and Waltham Abbey, was his elaboration of the system of manufacture and employment of gun-cotton which has been in extensive use at the Government works with little if any modification for over eighteen years, and has been copied from us by France, Germany, and other countries. By reducing the partially purified gun-cotton fibre to pulp, as in the ordinary process of making paper, then completing its purification when in that condition, and afterwards converting the finely-divided explosive into highly compressed homogeneous masses of any desired form and size, very important improvements were effected in its stability, its uniformity of composition and action, and its adaptability to practical uses, a great advance being made in the exercise of control over the rapidity of combustion or explosion of the material.

No success had attended the experiments instituted in England with wound cannon cartridges of gun-cotton threads made according to von Lenk's plan; on the other hand, a number of results which at first sight appeared very promising were obtained at Woolwich in 1867–68 with bronze field-guns and cartridges built up of compressed gun-cotton masses arranged in different ways (with varied air-spaces, &c.) with the object of regulating the rapidity of explosion of the charge. But although the attainment of high velocities with comparatively small charges of the material, unaccompanied by any indications of injury to the gun, was frequent, it became evident that the fulfilment of the conditions essential to safety to the arm were exceedingly difficult to attain with certainty, and appeared indeed to be altogether beyond absolute control, even in so small a gun as the twelve-pounder. Military authorities not being, in those days, alive to the advantages which might accrue from the employment of an entirely smokeless explosive in artillery, the lecturer received no encouragement to persevere with experiments in this direction, and the same was the case with respect to the possible use of a smokeless explosive in military small arms, with which, however, far more promising results had at that time been obtained at Woolwich.

Abel's system of preparing gun-cotton was no sooner elaborated than its application to the production of smokeless cartridges for sporting purposes was achieved with considerable success by Messrs. Prentice, of Stowmarket. The first gun-cotton cartridge, which found considerable favour with sportsmen, consisted of a roll of felt-like paper composed of gun-cotton and ordinary cotton, and produced from a mixture of the pulped materials. Afterwards a cylindrical pellet of slightly compressed gun-cotton pulp was used, the rapidity of explosion of which was retarded, while it was at the same time protected from absorption of moisture, by impregnation with a small proportion of india-rubber. Neither of these cartridges afforded promise of sufficient uniformity of action to fulfil military requirements, but after a series of experiments which the lecturer made with compressed gun-cotton arranged in various ways, very promising results were attained, especially with the Martini-Henry rifle and a charge of pellet-form, the rapidity of explosion of which was regulated by simple means.

A sporting powder which was nearly smokeless had, in the meantime, been produced by Colonel Schultze, of the Prussian Artillery, from wood cut up into very small cube-like fragments, converted into a mild form of nitro-cellulose after a preliminary purifying treatment, and impregnated with a small portion of an oxidizing agent. Subsequently the manufacture of the Schultze powder was considerably modified; it was converted into the granular form, and rendered considerably more uniform in character and less hygroscopic, and it then bore considerable resemblance to the E.C. powder, a granulated nitro-cotton powder, produced, in the first instance, at Stowmarket, and consisting of a less highly nitrated cotton than gun-cotton (trinitrocellulose), incorporated in the pulped condition with a somewhat considerable proportion of the nitrates of potassium and barium, and converted into grains through the agency of a solvent and a binding material. Both of these powders produced some smoke when fired, though the amount was small in comparison with that from black powder. They did not compete with the latter in regard to accuracy of shooting, when used in arms of precision, but they are interesting as being the forerunners of a variety of so-called smokeless powders, of which gun-cotton or nitro-cotton is the basis, and of which those of Johnson and Borland, and of the Smokeless Powder Company, are the most prominent in this country.

In past years, both camphor and liquid solvents, such as acetic ether and acetone for gun-cotton, and mixtures of ether and alcohol for nitro-cotton, have been applied to the hardening of the surfaces of compressed masses or granules of those materials, by von Förster and others, with a view to render them non-porous, and in the E.C. powder manufacture the latter solvent was thus applied to harden the powder-granules. In the Johnson-Borland powder camphor is applied to the same purpose; in smokeless powders of French and German manufacture acetic ether and acetone have been used, and the solvent has been applied not merely to harden the granules or tablets of the explosive, but also to convert the latter into a homogeneous horn-like material.

Much mystery has surrounded the nature and origin of the first smokeless powder adopted, apparently with undue haste, by the French Government, for use with the Lebel magazine rifle. A few particles of the Vieille powder, or *Poudre B*, were seen by the lecturer about two years ago, and very small specimens appear to have fallen into the hands of the German Government about that time. They were in the form of small yellowish-brown tablets of about 0·07 inch to 0·1 inch square, of the thickness of stout notepaper, and had evidently been produced by cutting up thin sheets of the material. They appeared to contain, as an important ingredient, picric acid (the basis of "mélinite") a substance extensively used as a dye, and obtained by the action of nitric acid, at a low temperature, upon carbolic acid and cresylic acid, constituents of coal tar. Originally produced by the action of nitric acid upon indigo, and afterwards by similar treatment of Botany Bay gum, it was first known as carbazotic acid, and is one of the earliest of known explosives of organic origin. When sufficiently heated, or when set light to, it burns with a yellow smoky flame, and even very large quantities of it have been known to burn away somewhat fiercely, but without exploding. Under certain conditions, however, and especially if subjected to the action of a powerful detonator, it explodes with very great violence and highly destructive effects, as pointed out by Sprengel in 1873, and recent experiments at Woolwich have shown that it does this even, as in the case of gun-cotton, when it contains as much as 15 per cent. of water. It is no longer a secret that picric acid at any rate forms the basis of the much-vaunted and mysterious explosive for shells for which the French Government were said to have paid a very large sum of money, and the destructive effects of which have been described as nothing less than marvellous. M. Turpin patented, in 1875, the use of picric acid alone as an explosive for shells and for other engines of destruction, and whether or not his claims to be the inventor of mélinite are valid, there appears no doubt that his patent in France was the starting-point of the development and adoption of that explosive.

The attention thus directed in France to the properties of picric acid appears to have given rise to experiments resulting in its employment as an ingredient of the first smokeless powder (*Poudre B*) adopted for the French magazine rifle.

The idea of employing picric acid preparations as explosive agents for propulsive purposes originated with Designolle about twenty years ago, but no useful results attended the experiments with the particular mixtures proposed by him. It is certain that the recent adaptation of that substance in France was of a different character, and that, promising as were the results of the new smokeless powder, of which it formed an ingredient, and of which a counterpart was made the subject of experiments at Woolwich about three years ago, its deficiency in the all-essential quality of stability must have been at any rate one cause of its abandonment in favour of another form of smokeless powder, which there is reason to believe is of more simple character.

In Germany, the subject of smokeless powder for small arms and artillery was being steadily pursued in secret, while the sensational reports concerning *Poudre B* were spread about in France, and a small-arm powder, giving excellent results in regard to ballistic properties and uniformity, was elaborated at

the Rottweil powder-works, and appears to have been adopted into the German service for a time, but its first great promise of success seems to have failed of fulfilment through defects in stability.

Reference has already been made to the conversion of gun-cotton (trinitrocellulose), and to mixtures of it with less explosive forms of nitrated cotton (or nitrated cellulose of other description), by the action of solvents into horn-like materials. These are in the first instance obtained in the form of gelatinous masses, which, prior to the complete evaporation or removal of the solvent, can be pressed or squirted into wires, rods, or tubes, or rolled or spread into sheets; when they have become hardened, they may be cut up into tablets or into strips or pieces of size suitable for conversion into charges or cartridges. Numerous patents have been secured for the treatment of gun-cotton, nitro-cotton, or mixtures of these with other substances, by the methods indicated; but in this direction the German makers of the powder just now referred to seem to have secured priority. Experiments were made about a year and a half ago with powder produced in this way at Woolwich, and the Wetteren Powder Company in Belgium has also manufactured so-called paper powders, or horn-like preparations, of the same kind, which were brought forward as counterparts of the French small-arm and artillery smokeless powder.

Mr. Alfred Nobel, to whom the mining world is so largely indebted for the invention of dynamite, and of other very efficient blasting agents of which nitro-glycerine is the basis, was the first to apply the latter explosive agent, in conjunction with one of the lower products of nitration of cellulose, to the production of a smokeless powder. The powder bears great resemblance to one of the most interesting of known violent explosives, also invented by Mr. Nobel, and called by him blasting gelatine, in consequence of its peculiar gelatinous character. When the nitro-cotton is impregnated and allowed to digest with nitro-glycerine, it loses its fibrous nature and becomes gelatinized while assimilating the nitro-glycerine, the two substances furnishing a product which has almost the character of a compound. By macerating the nitro-cotton with from 7 to 10 per cent. of nitro-glycerine, and maintaining the mixture warm, the whole soon becomes converted into a plastic material from which it is very difficult to separate a portion of either of its components. This preparation, and certain modifications of it, have acquired high importance as blasting agents more powerful than dynamite, and possessed of the valuable property that their prolonged immersion in water does not separate from them any appreciable proportion of nitro-glycerine.

In the earlier days of the attempted application of blasting gelatine to military uses, in Austria, when endeavours were there made to render the material less susceptible of accidental explosion on active service (as by the penetration of bullets or shell fragments into transport waggons containing supplies of the explosive), this result was achieved by Colonel Hess by incorporating with the components a small proportion of camphor, a substance which had then, for some time past, played an important part in the technical application of nitro-cotton to the production of the remarkable substitute for ivory, horn, &c., known as xylenite. By incorporating with nitro-glycerine a much larger proportion of nitro-cotton than used in the production of blasting gelatine, and by employing camphor as an agent for promoting the union of the two explosives, as well as, apparently, for deadening the violence, or reducing the rapidity of explosion of the product, Mr. Nobel has obtained a material of almost horn-like character, which can be pressed into pellets or rolled into sheets while in the plastic condition, and which compares favourably with the gun-cotton preparations of somewhat similar physical characters just referred to, as regards ballistic properties, stability, and uniformity, besides being almost absolutely smokeless. The retention in its composition of some proportion of the volatile substance camphor, which may gradually be reduced in amount by evaporation, renders this explosive liable to undergo some modification in its ballistic properties in course of time; it is believed that this point has been dealt with by Mr. Nobel, and accounts from Italy speak favourably of the results of trials of his powder in small arms, while Mr. Krupp is reported to be carrying on experiments with it in guns of several calibres.

The Government Committee on Explosives, in endeavouring to remedy the above defect of Nobel's original powder, were led by their researches to the preparation of other varieties of nitro-glycerine powder, which, when applied in the form of wires or rods, made up into sheaves or bundles, have given, in the service small-bore rifle, excellent ballistic results. The most promising of them, which fulfils, besides, the conditions of smokelessness and of stability, so far as can be guaranteed by the application of special tests of exposure to elevated temperatures, &c., is now being submitted to searching experiments with the view of so applying it in the arm as to overcome certain difficulties attending the employment, in a very small-bore rifle, of an explosive developing much greater energy than the black-powder charge, which therefore gives very considerably higher velocities even with much smaller charges, and consequently heats the arm much more. Thus, the service black-powder charge furnishes, with the small-bore rifle, an average (and variable) velocity of 1800 f.s., together with pressures ranging from 18 to 20 tons per square inch; on the other hand, with considerably less of the powder referred to, there is no difficulty in securing a very uniform velocity of about 2200 f.s. with pressures not exceeding 17 tons, while velocities as high as 2500 f.s. are obtainable with pressures not greater than the maximum allowed with the black-powder charge.

It is obvious, from what has already been said respecting the causes of the erosive action of powder in guns, that comparatively considerable erosive effects would be expected to be produced by powders of high energy as compared with black powder. Moreover, the freedom of the products of explosion from any solid substances, and consequently the absence of any fouling or deposition of residue in the arm, causes the heated surfaces of the projectile and of the interior of the barrel to remain clean, and in a condition, therefore, very favourable to close adherence together. If to these circumstances be added the fact that the behaviour of the smokeless powder has to be adapted to suit an arm, a cartridge, and a projectile originally designed for use with black powder, it will be understood that the devising of an explosive which shall be practically smokeless, sufficiently stable, and susceptible of perfectly safe use in the arm under all service conditions, easy of manufacture, and not too costly, is, after all, but a small part of the difficult problem of adapting a smokeless powder successfully to the new military rifle—a problem which, however, appears to be on the near approach to satisfactory solution.

The experience already acquired in guns ranging in calibre from 1·85 inches to 6 inches, with the smokeless powder devised for use in our service, has been very promising, and indicates that the difficulties attending its adaptation to guns designed for black powder are likely to prove considerably less than in the case of the small arm. But here, again, the circumstances that much smaller charges are required to furnish the same ballistics as the service black-powder charges, and that the comparatively gradual and sustained action of the new powder gives rise to lower pressures in the chamber of the gun, and higher pressures along the chase, demonstrate that the full utilization of the ballistic advantages, and the increase in the power of guns of a given calibre and weight with the new form of powder, are only attainable by some modifications in the designs of the guns—such as a reduction in size of the charge-chamber, and some additions to the strength, and perhaps, in some cases, of the length, of the chase.

When, however, the smokeless powder has been adapted with success in all respects to artillery, from small machine-guns to guns of comparatively heavy calibre, and when its ballistic advantages have been fully utilized in guns of suitable design, it will remain to be determined how far such a powder—undeniably of much more sensitive constitution than black powder, or any of its modifications—will withstand, unchanged and unharmed, the various vicissitudes of climate, and the service storage-conditions in ships and on land in all parts of the world—a condition essential to its adaptability to naval and military use, and especially to the service of our Empire; and whether sufficient confidence can be placed in its stability for long periods under these extremely varied conditions to warrant the necessary freedom from apprehension of possible danger, emanating from within the material itself, to allow of its being substituted for black powder wherever its use may present advantages.

Possible it might be, that the storage, with perfect safety, of such a powder in ships, forts, or magazines might demand the adoption of precautionary measures tending to place comparatively narrow limits upon the extent of its practicable service applications; even then, however, an imperative need for the introduction of special arrangements to secure safety and immunity from deterioration may be of small importance as

compared with the great advantages which the provision of a thoroughly efficient smokeless powder may secure to the possessor of it, especially in naval warfare.

That the opinions respecting the importance of such advantages are founded upon a sound basis, one can hardly doubt, after the views expressed by several of the highest military and naval authorities, although opinions as to their extent may differ very considerably even among such authorities.

The accounts furnished from time to time from official and private sources of the effects observed, at some considerable distance, by witnesses of practice with the smokeless powders successively adopted in France, have doubtless been regarded by military authorities as warranting the belief that the employment of such powders must effect a great revolution in the conduct of campaigns. Not only have the absence of smoke and flame been dwelt upon as important factors in such a revolution, but the recorders of the achievements of smokeless powder—whose descriptions have doubtless been to some extent influenced by the vivid pictures already presented to them of what they *should* anticipate—have even been led to make such explicit assertions as to the *noiselessness* of these powders, that high military authorities have actually been thereby misled to portray, by vivid word-painting, the contrast between the battles of the future and the past;—to imagine the terrific din caused by the discharge of several hundred field-guns and the roar of musketry in the great battles of the past, giving place to noise so slight that distant troops will no longer receive indications where their comrades are engaged, while sentries and advanced posts will no longer be able to warn the main body of the approach of an enemy by the discharge of their rifles, and that battles might possibly be raging within a few miles of columns on the march without the fact becoming at once apparent to them.

It is somewhat difficult to conceive that, in these comparatively enlightened days—an acquaintance with the first principles of physical science having for many years past constituted a preliminary condition of admission to the training establishments of the future warrior—the physical impossibility of such fairy tales as appear to be considered necessary in France for the delusion of the ordinary public, would not at once have been obvious. Yet, even in professional publications in Germany, where we are led to expect that the judgment of experts would be comparatively unlikely to be led astray through lack of scientific knowledge, we have, during the earlier part of last year, read, in articles upon the influence of smokeless powder upon the art of war (based evidently upon the reports received from France), such passages as these:—"The art of war gains in no way as far as simplicity is concerned; on the contrary, it appears to us that the absence of so important a mechanical means of help as *noise* and smoke were to the commander, requires increased skill and circumspection in addition to the qualities demanded by a general. . . ." "The course of a fight will certainly be mysterious, on account of the *relative stillness* with which it will be carried on."

In an amusing article, in imitation of the account of the Battle of Dorking, which appeared in the *Deutsche Heeres Zeitung* of April last, the consternation is described with which a battalion receives the information from a wounded fugitive from the outposts that the enemy's bullets have been playing havoc among them, without any visible or audible indications as to the quarter of attack. Later in the year, and especially since the manœuvres before the German and Austrian Emperors, when the employment of the new smokeless powder was the event of the day, the absurdity of the assertions as to the noiselessness of the new powders became a theme for strong observations in the German service papers; the assumed existence of a noiseless powder was ridiculed as a thing equally impossible with a recoil-less powder; the violence of the report, or explosion, produced upon the discharge of a firearm being in direct relation to the volume and tension of the gaseous matter projected into the surrounding air.

The circumstance that blank ammunition was alone used in the smokeless powder exhibition at the German manœuvres, may have served to lend some support to the assertions as to *comparatively* little noise made by the powder—the report of blank cartridges being slight, on account of the small and lightly confined charges used. It is said that the sound of practice with blank ammunition at the German manœuvres, was scarcely recognized at a distance of 100 metres. In a recently published pamphlet on the results of employment of the latest German smokeless powder in the manœuvres, it is stated, on the other hand, that the difference between the violence of the report of the new powder and of black powder is scarcely perceptible; that it is sharper and more ringing, but not of such long duration. This description accords exactly with our own experience of the reports produced by different varieties of smokeless powder, and of the lecturer's earlier experience with gun-cotton charges fired from rifles and field guns. The noise produced by the latter was decidedly more ringing and distressing to the ear in close proximity to the gun, but also of decidedly less volume than the report of a black-powder charge, when heard at a considerable distance from the gun.

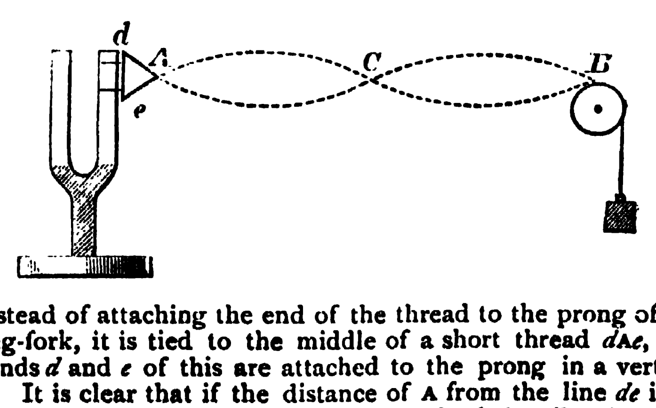
As regards smokelessness, the present German service powder is not actually smokeless, but produces a thin, almost transparent, bluish cloud, which is immediately dissipated. Independent rifle-firing was not rendered visible by the smoke produced at a distance of 300 metres, and at shorter ranges the smoke presented the appearance of a puff from a cigar. The most rapid salvo-firing during the operations near Spandau did not have the effect of obscuring those firing from distant observers.

That, in future warfare, if smokeless or nearly smokeless powders have maintained their position as safe and reliable propelling agents for small arms and field artillery, belligerents of both sides will be alike users of them, there can be no doubt. The consequent absence of the screening effect of smoke—which, on the one hand, removes an important protection and the means of making rapid advances or sudden changes of position in comparative safety, and, on the other hand, secures to both sides the power of ensuring to the fullest extent accuracy of shooting, and of making deadly attack by individual fire through the medium of cover, with comparative immunity from detection—can scarcely fail to change more or less radically many of the existing conditions under which engagements are fought.

As regards the naval service, it is especially and, at present at any rate, exclusively for the new machine and quick-firing guns that a smokeless powder is wanted; for such service the advantages which would be secured by the provision of a reliable powder of this kind can scarcely be over-estimated, and their realization within no distant period may, it is believed, be anticipated with confidence.

NOTE ON MR. MELDE'S VIBRATING STRINGS.

THE effect of Mr. Melde's pretty experiments with the vibrating stretched thread attached to one of the prongs of a tuning-fork is often spoiled to the spectators by the unfavourable plane of vibration assumed by the thread. A very simple device removes this inconvenience, and enables the operator to suit his own choice for the plane of vibration. The accompanying sketch sufficiently explains itself, and shows the arrangement for restricting the vibrations to the vertical plane.



Instead of attaching the end of the thread to the prong of the tuning-fork, it is tied to the middle of a short thread *dAe*, and the ends *d* and *e* of this are attached to the prong in a vertical line. It is clear that if the distance of A from the line *de* is an appreciable part of the quarter wave-length of the vibration, and AB is an integral multiple of the half wave-length, vibration is possible only in the vertical plane. For in the horizontal plane this rate of vibration is impossible, A being not a fixed point of the thread for vibration in this plane, and the length from the prong to the pulley being not an integral multiple of the half wave-length of vibration. And in any other plane the vibration, if possible, would be compounded of two, viz. of the vertical which is possible and of the horizontal which is impossible.

The most convenient form of fixture for the short thread *dAe*, is a light steel wire with an eye at each end, lashed to the prong

with two turns of fine thread. The plane of vibration can then be easily adjusted to suit the spectators by sluing the wire in its lashing.

Note.—The triangular thread *dAe* should be of the same quality as the vibrating length. If it is much heavier length for length the arms of the triangle may become half wave-lengths of the vibration for the tension employed, and then they lose their control over the plane of vibration.

The arrangement has its own worth, independently of the aid it lends to visible effect, as an illustration of the suppression of all half wave-lengths which are not true sub-multiples of the vibrating length of the cord. When the fork is moved from its position in the figure to bring up the line *de* to the position of A, the vertical vibrations are suppressed, and only the horizontal vibrations are possible. W. SIDGREAVES.

EIGHTH CONGRESS OF RUSSIAN NATURALISTS.

THE eighth Congress of Russian Naturalists and Physicians was opened on January 9 at St. Petersburg, and was a great success. It was attended by no fewer than 2000 members, half of whom came from the provinces, and at the three general public sittings (corresponding to the sittings of the British Association devoted to the delivery of the Presidential addresses), as well as the meetings of the Sections, the public were well represented. At the first general sitting, Prof. Mendeleeff delivered a most interesting address on the methods of natural science as applied to the study of prices. His parallels between the prices of goods and the specific weights and specific volumes of chemical bodies were very suggestive. The next address, by Prof. Sklifasovsky, was on the wants of Russian medical education. At the second general sitting, Prof. Stoletoff spoke of ether and electricity. Prof. Famintzyn's address on the psychical life of the simplest representatives of living beings, partly based upon his own recent researches into the intelligence of Infusoria, was full of facts as to the means used by various micro-organisms in attack and defence. Prof. Wagner dealt with the physiological and psychological views upon hypnotism, and Prof. Gustavson spoke of the micro-biological bases of agronomy.

The work of the Sections was very varied, and will be fully reported in the Diary of the Congress, the publication of which began during the sitting of the Congress, and will be continued till a full account has been produced.

The Sections of Geography and Anthropology, Hygiene, and partly of Agronomy, were most largely attended, and many interesting communications were made in them. At the combined sittings several important questions were raised as to the geography of Russia, its meteorology, and the bearings of a scientific study of climate and soil upon agriculture.

The following communications relative to geography and anthropology were especially worthy of note. Captain Makaroff reported the results of his careful measurements as to the differences of level of various seas of Europe. Taking the average level of the Atlantic Ocean opposite Lisbon for zero, he found that the level of the western parts of the Mediterranean is 434 millimetres below zero, its eastern part, − 507 millimetres; the Ægean Sea, − 563 millimetres; the Marmora Sea, from − 360 to − 291 millimetres; while the Black Sea is + 246 millimetres—that is, higher than the Lisbon zero; the western part of the Baltic, + 259 millimetres; its eastern part, + 254 millimetres; and the Gulf of Finland, + 415 millimetres. Dr. Blum's anthropological measurements amidst twelve different tribes of the Caucasus show that there are no pure races in Caucasia, all of them being mixtures between Semitic and Indo-European races. Like conclusions were arrived at by M. Kharuzin as regards the Bashkires, who proved to be a mixed race, presenting features both of the Mongolian and the Caucasian races.

Prof. Klossovsky's researches into the variations of level and temperature in the coast region of the Black Sea are most valuable, as they are based on accurate measurements made since 1879 at 16 different places. They fully disclose the importance of atmospheric pressure upon the level of the Black Sea, and it is worthy of note that the passage of a cyclone over Odessa resulted in a rise of the level of the sea by fully 5 feet over the average, followed by a sinking of the level by fully 7 feet, in accordance with the variations of atmospheric pressure.

Dr. Orzanski's extensive anthropological researches amidst the population of Russian prisons, and his numerous measurements, show no difference between the supposed "criminal's skull" and the average Russian skull. Numerous photographs were exhibited to illustrate this conclusion, so different from those arrived at by Dr. Lombroso.

Two new periodicals—one of them devoted to Russian natural science, and the other to meteorology—were founded while the Congress was at work. The meeting came to an end on January 20.

The Congress hoped to obtain from the Government permission to appoint a permanent Board, and thus to lay the foundation of a Russian Association for the Advancement of Science.

TECHNICAL EDUCATION IN ELEMENTARY SCHOOLS.

THE Committee of the National Association for the Promotion of Technical and Secondary Education have submitted to the Education Department the following suggestions for the modification of the Code as regards elementary technical education:—

A.—*Drawing.*

(1) Drawing to be introduced in infant schools, at least for boys.

(2) Drawing to be made compulsory in boys' schools.

(3) The Minute requiring cookery to be taught in girls' schools as a condition of receiving grant for drawing, to be repealed.

B.—*Object Lessons.*

(4) No school to be recognized as efficient which does not provide in the three lower standards a graduated scheme of object lessons in continuation of Kindergarten instruction in the infant school.

C.—*Science.*

(5) In order to encourage science as a class subject, the clause requiring English as one of the class subjects to be cancelled, and the teaching of science as a class subject to be further encouraged in the upper standards by an additional grant.

(6) Scholars of any public elementary school to be allowed to attend science classes held at any place approved by the inspector, and such attendance to count as school attendance.

(7) Examinations in science to be conducted orally, and not on paper, especially in the first five standards. If the inspection is satisfactory, an attendance grant of 4*s*. to be made for scientific specific subjects.

(8) Managers to be encouraged to submit alternative courses of instruction in specific subjects under Art. 16 (Code 1888). Such subjects to receive a grant on the same principle as the subjects enumerated in Art. 15.

[Art. 16. "Any other subject *other than those mentioned in Art.* 15, may, if sanctioned by the Department, be taken as a specific subject, provided that a graduated scheme of teaching it be submitted to and approved by the inspector."

But Art. 109 (*g*) which lays down the condition for grants, says, "The specific subjects which may be taken *are those enumerated in Art.* 15."]

(9) Grants to be made towards apparatus for science teaching and school museums.

D.—*Manual Instruction.*

(10) Manual instruction to be introduced in boys' schools, corresponding to needlework for girls.

(11) Instruction in the use of *simple tools* to be introduced in the higher standards as a specific subject, and grants to be paid thereon.

(12) Provision to be made for the introduction of *elementary modelling* in connection with the teaching of drawing, and a grant to be made in connection therewith.

(13) Instruction in *laundry work* to be encouraged in girls' schools, so far as practicable, as a part of domestic economy.

E.—*Evening Schools.*

(14) The clause providing that "No scholar may be presented for examination in the additional subjects alone" to be cancelled, to enable scholars to earn grants though not receiving instruction in the standard subjects.

(15) The number of "additional subjects" which may be taken to be increased from two to four.

F.—*Training Colleges.*

(16) Day Training Colleges and a third year of training to be recognized. The Universities and local University Colleges to be utilized for the training of teachers, where suitable arrangements can be made.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following appointments of Electors to Professorships have been made. Each Board consists of eight members, and it is provided by the Statutes that at least two members shall not be resident in the University or officially connected with it. In certain cases more than two such members have been voluntarily chosen by the Senate.

Arabic: Prof. Bensly, *Music:* Sir George Grove; *Chemistry:* Dr. E. Frankland, F.R.S.; *Plumian of Astronomy;* Mr. W. D. Niven; *Anatomy:* Dr. Huxley, F.R.S.; *Botany:* Prof. D. Oliver, F.R.S.; *Woodwardian of Geology:* Dr. A. Geikie, F.R.S.; *Jacksonian of Natural Philosophy:* Dr. Hugo Müller, F.R.S.; *Mineralogy:* Sir W. Warington Smyth, F.R.S.; *Political Economy:* Mr. R. H. Inglis Palgrave, F.R.S.; *Zoology and Comparative Anatomy:* Dr. Huxley, F.R.S.; *Sanskrit:* Prof. Aufrecht and Mr. R. A. Neil; *Cavendish of Physics:* Sir William Thomson, F.R.S.; *Mechanism:* Mr. W. Airy; *Downing of Law:* Mr. Justice Denman; *Downing of Medicine:* Dr. Richard Quain, F.R.S.; *Physiology:* Prof. Burdon Sanderson, F.R.S.; *Pathology:* Dr. J. F. Payne; *Surgery:* Sir James Paget, F.R.S; *Chinese:* Dr. Peile.

Prof. Robertson Smith being unable on account of the state of his health to lecture this term, Mr. A. A. Bevan, B.A., of Trinity College, has been appointed his deputy.

The Syndicate appointed to consider the probable expense of maintaining and working the great telescope offered to the University by Mr. Newall, report that a capital sum of £2225, and an annual expenditure of £400 will probably be required. They report further that the Sheepshanks Special Fund, founded in 1863 for the benefit of the observatory, will probably be able to furnish a capital sum of £1000, and an annual grant of £100, towards the expenses of the Newall telescope. The remainder, or £1225 at once, and £300 a year, will have to be provided from other sources; but whence is by no means apparent.

SCIENTIFIC SERIALS.

Revue d'Anthropologie, troisième série, tome iv., sixième fasc. (Paris, 1889).—Researches on the cephalic index of the Corsican population, by Dr. A. Fallot (of Marseilles). In an earlier number of this review, the author drew attention to the very appreciable alteration which the cephalic index had undergone in recent times among the inhabitants of Marseilles. Thus in one group of living subjects, born at the beginning of the century, he found that 21 per cent. exhibited an index of 84, while in another group, consisting of men of middle age, this number occurred only in the ratio of 7 per cent. This remarkable difference led the author to continue his determinations of the cephalic index among different communities. With this object in view, he last year visited Corsica, and in the present article we have the results of his craniometric determinations in this island, where from its peculiar geographical position and geognostic features, the inhabitants have preserved a permanence of type, and a homogeneity of ethnic characteristics, probably unequalled in any other European nation. Indeed so inconsiderable have been the changes effected in recent times in the Corsican population, that the observations made by Volney, in 1793, on the country and the people, apply almost equally well to their present condition. At the same time so little addition has been made since that period to our previously imperfect knowledge of Corsica, that Dr. Fallot's observations supply a valuable contribution to ethnological inquiry. All his determinations tend to demonstrate the great uniformity of cranial type and characters in the people. Thus while 54 per cent. of the population present a cephalic index varying from 75 to 78, not more than 13 per cent. gave an index above 80, while in only one out of 200 cases the index amounted to 86, and hence he assumes the mean index to be 76·5. He found that this uniformity was the greatest in the interior of the island, and more especially in the *département* of Corte; while at Bastia, in the extreme north, the cranial characteristics exhibited more variety, and afforded evidence of an admixture with foreign elements, a subbrachycephalic type supplanting the more general Corsican character of dolichocephalism. In the preponderance of this latter type Dr. Fallot thinks we have incontrovertible evidence against the opinion of Lauer, that the Corsicans are of Ligurian descent, and he believes that they may be more correctly characterized as an offshoot from the old Iberian races. The author gives numerous useful tables, and his brief summary of the history of the island is clear and instructive. From his observations on the geological conformation of the island we learn how numerous spurs, thrown off from the central high mountain range, have enclosed and isolated the several valleys, cutting off villages and settlements from their neighbours, and thus exerted so strong an influence upon the character and habits of the inhabitants, that the physical features of the island may be said to supply the key to its history. From the author's observations it may be assumed that in the mountain districts of the interior the genuine Corsican cranial type has been best preserved.—On infibulation, and other mutilations practised among the littoral tribes of the Red Sea, and the Gulf of Aden, by Dr. Jousseaume. The author describes at length the methods by which these processes are effected, and considers that whatever may have been their original motive they are in no way at present connected with religious observances, but are simply carried on from generation to generation as survivals of ancient barbarous customs.—On modern crania in Montpellier, by M. de Lapouge. In 1888 the author obtained 150 tolerably perfect skulls, which had been recovered from the soil of a cemetery at Montpellier used for interments from the seventeenth century until it was closed in 1830. An examination of the author's elaborate series of comparative craniometric measurements shows that the mean for the cephalic index of these skulls, viz. 78·3, is the lowest as yet observed in France, while their general cranial characters have less affinity with a French, than a North African type.—Prehistoric Scandinavia, by M. I. Undset. This is a sequel to a paper published in this review in 1887, the author now bringing his survey of the progress of northern palæontological science up to the present time.

THE *American Meteorological Journal* for December contains:—An article by W. M. Davis and C. E. Curry, on Ferrel's convectional theory of tornadoes; his theory, which is remarkably simple, is based on the occurrence of an ascensional movement in the tornado-whirl. The authors state that this fact seems too well established to admit of a doubt, although Faye and others in Europe, and Hazen in the United States, have questioned it. The paper contains graphical illustrations of the instability caused by convection.—Tornado chart of the State of Indiana, by Lieutenant J. P. Finley, compiled from statistics for seventy-one years ending 1888. The average yearly frequency is 4·5 storms. The month of greatest frequency is May.—Theory of storms, based on Redfield's laws, by H. Faye, continued from the November number, and dealing with the mechanics of whirls in flowing water, and with the upper currents of the atmosphere; the conclusion being that cyclones are whirls, originating in the upper regions of the air.—A continuation of the article on the meteorology at the Paris Exhibition, by A. L. Rotch, describing the meteorological instruments in the foreign sections.—The conclusion of Dr. F. Waldo's interesting discussion of wind velocities in the United States, with charts of "isanemonals" for January, July, and the year. The fact that the curves can be drawn with general symmetry shows that there is some uniformity in the exposure of the anemometers for *like* regions. The author points out that the effect of the Rocky Mountains seems to make itself felt on the winds to a distance of 200 or 300 miles to the eastward.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 19, 1889.—"Some Observations on the Amount of Luminous and Non-Luminous Radiation emitted by a Gas-Flame." By Sir John Conroy, Bart.

These experiments show—

(1) that 3 millimetres of glass and 10 centimetres of water transmit a small portion of the non-luminous radiation of an Argand gas-burner, but that, when the thickness of the water is increased to 15 centimetres, the transmitted radiation consists exclusively, or almost exclusively, of those kinds of radiation which affect the eye as light.

(2) That, with the form of apparatus employed (a thermopile and galvanometer), there is no measurable difference between the diathermancy of pure water and of a solution of alum.

(3) That the radiation from an Argand gas-burner consists of about 1·75 per cent. luminous and 98·25 per cent. non-luminous radiation.

January 30.—"On outlying Nerve-cells in the Mammalian Spinal Cord." By Ch. S. Sherrington, M.A., M.B., &c. Communicated by Prof. M. Foster, Sec. R.S.

Gaskell has shown that in the cord of the alligator scattered nerve-cells are to be seen at the periphery of the lateral column. Although nerve-cells appear to be absent from that position in the spinal cord of Mammalia as represented by the rabbit, cat, dog, calf, monkey, and man, yet there are in these animals isolated nerve-cells present in the white matter of the cord, not only in the deeper portions of the lateral column, but in the anterior and posterior columns as well.

In the anterior columns occasional nerve-cells, of the multipolar kind, lie among those fibre-bundles which pass between the deeper mesial border of the anterior horn and the anterior commissure at the base of the anterior fissure. They, in the instances observed, are smaller than the large cells characteristic of the anterior horn, and lie with two of the processes directed parallel with the horizontal transverse fibres among which they are placed.

In the lateral column, of the spinal cord of man and the other animals named above, it is common to find outlying members of the group of small cells of the lateral horn, Clarke's tractus intermedio-lateralis, situated in the white matter, distinctly beyond the limits of the grey. Some outlying cells here are placed at a great distance from the grey. They are generally placed upon, or at least in close connection with, the fine connective-tissue septa which pass across the white matter. It is probable that the cells are connected with the medullated nerve-fibres running along these septa.

In the part of the lateral column adjacent to the lateral reticular formation numerous nerve-cells are to be found among the interlacing bands of nerve-fibres. These are often fusiform, but in many cases multipolar; they are for the most part small, but occasional large individuals can be found; the latter would appear always to be multipolar. Where the lateral column comes into contact with the lateral limb of the substantia gelatinosa of the caput cornu posterioris ganglion-cells can frequently be seen in it. The larger axis of these cells is parallel to the outline of the caput cornu.

In the posterior columns outlying nerve-cells are also to be found, especially in the human cord. They are best seen in the upper lumbar and lower dorsal regions. They are large, measuring in some instances 70 μ across. In appearance they closely resemble the cells of Clarke's column. They are nearly always of broadly ovate shape. They appear always to lie on or in close relation to those horizontal bundles of nerve-fibres which curve in a ventro-lateral direction from the depth of the extero-posterior column into the grey matter in the neighbourhood of the posterior vesicular group. The longer axis of the cell is placed parallel to the nerve-fibres it lies upon or among. Where a process from the bipolar cell-body can be followed, it disappears in a direction which is that of the surrounding nerve-fibres.

With regard to the cells existing among fibres passing to the white commissure of the cord, it is legitimate to consider their presence as evidence in favour of the view that some of the cells of the median portion of the ventral grey horn are directly connected with medullated fibres passing to or from the opposite half of the cord by way of the anterior commissure.

The cells in the lateral column outside the lateral horn may be taken to point to the connection of the intermedio-lateral group of Clarke with the nerve-fibres which radiate in bundles from the grey matter of that region into the lateral column. Concerning some of the outlying cells in the more dorsal portion of the lateral column, the same inferences may be drawn; and some of them would seem to be connected with fibres of the posterior roots that curve round the lateral aspect of the caput cornu posterioris. Of the outlying cells in the posterior column, if they are outlying members of Clarke's group, the relations which they suggest for that group are—

i. That the group is connected *directly* with certain of the median fibres of the posterior spinal roots—namely, those which after an upward course in Burdach's column plunge into the grey matter of the base of the posterior horn.

ii. That some at least of the cells of that group are interpolated, more or less immediately, into the course of medullated nerve-fibres of large calibre.

The question naturally arises, May not these cells in the posterior column of the Mammalian cord represent the bipolar cells discovered by Freud, in the cord of *Petromyzon planeri*, to be in direct communication with fibres of the posterior roots? If so, may Clarke's column be considered a portion of the ganglion of the posterior spinal nerve-root which has been retained in the interior of the spinal cord in the thoracic and certain other regions?

Royal Meteorological Society, January 15.—Annual Meeting.—Dr. W. Marcet, F.R.S., President, in the chair.—The Council, in their Report, congratulated the Fellows on the generally prosperous state of the Society; the past year's work, though not in any respect exceptional, having been thoroughly successful. The total number of Fellows is 550, being an increase of 25 on the previous year; the finances are improving, and the library is overflowing.—Mr. Baldwin Latham was elected President for the ensuing year.—The retiring President, Dr. Marcet, then delivered an address on "Atmospheric Dust," which he divided into organic or combustible, and mineral or incombustible. The dust scattered everywhere in the atmosphere, and which is lighted up in a sunbeam, or a ray from an electric lamp, is of an organic nature. It is seen to consist of countless motes, rising, falling, or gyrating, although it is impossible to follow any of them with the eye for longer than the fraction of a second. It is difficult to say how much of the dust present in the air may become a source of disease, and how much is innocuous. Many of the motes belong to the class of micro-organisms which are frequently the means of spreading infectious diseases. Many trades, owing to their dusty nature, are very unhealthy. Dust, when mixed with air, is inflammable and liable to explode. After giving several instances of explosions due to fine dust in flour mills and coal mines, Dr. Marcet referred to inorganic or mineral dust, and gave an account of dust storms and dust pillars in India. He then proceeded to describe volcanic dust, which consists mainly of powdered vitrified substances, produced by the action of intense heat. The so-called ashes or scoriæ shot out in a volcanic eruption are mostly powdered pumice, but they also originate from stones and fragments of rocks, which striking against each other, are reduced into powder or dust. Volcanic dust has a whitish-gray colour, and is sometimes nearly quite white. Dr. Marcet concluded with an account of the great eruption of Krakatão in August 1883. The address was illustrated by a number of lantern slides.

EDINBURGH.

Royal Society, January 20.—Sir W. Thomson, President, in the chair.—Prof. Tait communicated an obituary notice of Dr. Andrew Graham, R.N., by Mr. John Romanes, W.S.—The President gave a paper on electrostatic stress. A complete dynamical illustration of electro-dynamic action may be had in an elastic solid, homogeneous in so far as rigidity is concerned, permeated with pores of unalterable size containing liquid. These pores may be in part in communication with each other, and in part closed by elastic partitions. These cases correspond to conductors and non-conductors respectively. Electrostatic stress depends on the curvature and extension of the partitions. The law of capacity in the model is identical with that in conductors.—Prof. C. Michie Smith described the great eruption at Ban daisan, Japan, photographs being shown.—Prof. Tait read a paper, by Prof. Heddle, on a curious set of fog-bows.—Dr. Berry Haycraft gave an account of some experiments which extend our knowledge of volitionary movement and explain the production of the muscle and heart sounds.

PARIS.

Academy of Sciences, February 3.—M. Hermite in the chair.—On the nuclei of the great Comet II. of 1882, by M. F. Tisserand. From the presence of five bright points disposed in a straight line, it is evident that the matter was not uniformly

distributed in the head of this comet. There exist several centres of condensation with apparent diameters of 1" or 2", their mutual distances changing from time to time, but their position remaining constant in the same straight line, which revolves progressively round the principal nucleus. These conditions are specially favourable for the development of secondary nuclei, which the author regards as so many minor comets submitted to the attraction of the sun alone, moving in very elongated elliptical orbits with a common perihelion and different long axes, disposed, however, according to the same straight line. Hence the comet contained within itself the germs of disrupture, its elements in this respect resembling those of the 1843 and 1880 comets.—On the roots of an algebraic equation, by Prof. A. Cayley. Resuming the theory of the roots of the equation $f(u) = 0$, instead of the surface $c - z = P^2 + Q^2$, the author now studies the surface $(c - z)^2 = P^2 + Q^2$, taking into consideration the positive values only of z that are not greater than c. He hopes to apply this theory to the case of a cubic equation, where the calculations, however, are much more difficult.—Determination of regulated harmonic surfaces, by M. L. Raffy. Very few surfaces are known whose linear element is reducible to the harmonic form (Liouville's form). To find others, the author employs two distinct processes. The first consists in taking the analytical form of the co-ordinates of the surface in function of two parameters, and determining the unknown functions, so that the linear element may be harmonic; the second, in seeking for harmonic surfaces amongst those which may be generated by taking their linear element alone.—Solar observations for the last six months of 1889, by M. Tacchini. Excluding the month of August, the observations here tabulated for the spots and faculæ show that the period of calm has continued to the end of the year, and the observations already made for January 1890 show that this period still continues. The same result is shown in the case of the protuberances, so that we appear to have entered the period of absolute minimum.—On the propagation of sound, by MM. Violle and Vautier. These experiments, made with a cylindrical tube, lead to the inference that, whatever be the nature of the initial impulse, the sound-wave tends towards a simple, determined form, and this form once acquired, the various parts of the wave are propagated with a uniform velocity which must be regarded as the normal velocity of the sound. The velocity in the open air is greater than in a tube, where the influence of the walls causes a retardation in inverse ratio to the diameter, and exceeding 0·46 m. in a tube with diameter of 1 meter. The normal velocity of sound in a dry atmosphere at zero is 331·10 m., with probable error less than 0·10 m.—On the state of the magnetic field in conductors of three dimensions, by M. P. Joubin. The results of these researches, which agree with experience, show that the magnetic field produced by a current exists in the medium traversed by the electric flux as well as in the exterior medium.—On the mechanical actions of variable currents, by M. J. Borgman. In reproducing, with the limited resources of a laboratory, the interesting experiments exhibited by Prof. E. Thomson at last year's Exhibition, the author has obtained some fresh results, which are here described.—Results of the actinometric observations made at Kiev in 1888–89, by M. R. Savelief. These observations lead to the general conclusion that 63·5 per cent. of the annual solar heat reaching the earth is absorbed by the terrestrial atmosphere, only 36·5 arriving on the surface of the ground; in October the proportion is 41, in January and February 28 per cent. The maximum received on a fine day in the beginning of July is 610, and in December 87 calories on a given space.—On the compounds of the metals of the alkalies with ammonia, by M. Joannis. In continuation of his previous communication (*Comptes rendus*, cix. p. 900) the author describes some further experiments, which are totally at variance with the theory advanced by M. Bakhuis Roozeboom (*Comptes rendus*, cx. p. 134) to explain the phenomena already observed by M. Joannis.—On the combinations of ammonia and phosphuretted hydrogen with dichloride and dibromide of silicon, by M. Besson. With ammonia a solid, white, amorphous substance, of the formula $Si_2Br_4, 7NH_3$, is obtained, in all respects resembling the corresponding compound of the chloride. Phosphuretted hydrogen has no action on silicon dichloride at the ordinary temperature, but is absorbed at low temperatures. At $-60°$ C. the composition is approximately $Si_2Cl_4, 2PH_3$.—On the part played by certain foreign substances in iron and steel, by M. F. Osmond. The author here gives results for boron, nickel, copper, silicium, arsenic, and tungsten, reserving for a future paper full treatment of the subject.—On lussatite, a new crystallized variety of silica, by M. Er. Mallard. To the substance here described as nearly pure silica, the author gives the name of lussatite, from the deposits of bitumen at Lussat, near Pont-du-Château, where its properties may best be studied.—On the oxides of manganese, by M. Alex. Gorgeu. In this paper, the author studies the psilomelanes and wads, reserving for a future note the manganites, properly so called: hausmannite, acerdese, and braunite.—Papers were read by M. Paul Marchal, on the structure of the excreting organ in the prawn; by M. P. A. Dangeard, on the junction of stem and root in the gymnosperms; by M. Stanislas Meunier, on a new method of artificially producing ferriferous platinum with magnetic poles; and by M. Alexis de Tillo, on the hypsometric chart of European Russia.—M. Gilbert was nominated Corresponding Member of the Section for Mechanics in place of the late M. Broch.

BERLIN.

Physiological Society, January 17.—Prof. du Bois-Reymond, President, in the chair.—Dr. Weyl gave an account of experiments which he had made in conjunction with Dr. Kitasato on the biology of anaërobic Bacteria. Koch had only imperfectly overcome the difficulty in the way of a pure culture of these Bacteria, viz. the exclusion of atmospheric oxygen, by covering the plates on which they were being grown with films of mica. Livonius was more successful by means of a deep layer of Agar-Agar, and by replacing the air by an atmosphere of hydrogen. The speaker had endeavoured to arrive at the same result by mixing the material on which the cultivation was carried on with some substance which has an affinity for oxygen, and obtained good results with dioxyphenols and aldehydes, but more particularly with formate of soda. The members of the first class of substances, of which a large number were tried, had for the most part to be abandoned, for they exerted a toxic action on the Bacteria when they were employed in quantities sufficient to insure the complete absorption of oxygen. Very fine pure cultures of the anaërobic Bacteria of "quarter-evil" (*Rauschbrand*), of tetanus, and of malignant œdema, were obtained on Agar-Agar by the use of eikonogen and of formate of soda, and were exhibited to the meeting. By means of these pure cultures it was possible to demonstrate that the anaërobic Bacteria exert a powerful reducing influence; this was shown on preparations in which the culture-material was deeply coloured with indigo-blue, the latter being then reduced by the organisms to indigo-white. These simple methods of cultivation facilitate greatly the further investigation of these Bacteria.—Prof. Liebreich spoke on the function of the bladder in fishes. During his investigations of the inert layer on the upper surface of fluids, he had allowed a float whose specific gravity was slightly less than that of the fluid to ascend through the fluid, and observed that it came to rest a short distance below the surface and remained there. During these experiments the slight changes of temperature which are unavoidable in large masses of fluid produced irregularities which led him to study the phenomena exhibited by a "Cartesian diver." These are not correctly described in either the older original works on the subject or in the more recent textbooks of physics. The equilibrium of the diver is unstable for any given pressure exerted upon the elastic membrane which covers the upper end of the vessel in which he is contained. This the speaker proved, not only by developing the formulæ which hold good for a system composed partly of solids and partly of air when immersed in a liquid, but also by means of a series of striking experiments. When the attention is directed to the experiment, it may readily be noticed that it is impossible to keep the diver in a condition of rest at any given level by exerting a *uniform* pressure with the finger on the elastic membrane, but that in order to produce this result the pressure must be continuously varied. If the pressure is applied by a screw instead of the finger, the diver does not remain at rest. When the air is compressed until the specific gravity of the diver is slightly greater than that of the liquid, he sinks to the bottom and remains there, however great the air-pressure may be. If now he is drawn to the top of the liquid by means of a magnet attracting a small slip of iron attached to the diver, he similarly remains at rest at the surface. If, again, he is now drawn slightly down, he rises towards the surface again, when left to himself, until he reaches a level above which he no longer rises but now sinks to the bottom. This layer of fluid—such that when drawn above it he rises and when drawn down below it he sinks—may be called his "hydrosphere," or, in other words, it is a layer of liquid within the limits of which his specific gravity is unity. A fish possessed

of a swim-bladder is in exactly the same condition as the diver, for it also is in unstable equilibrium in the water. The fish can only remain at rest in the water by continually readjusting its "hydrosphere" by means of slight contractions of the bladder, and thus balancing itself in a position of rest. When the fish rises or sinks, or moves horizontally, the alterations of the swim-bladder and the changes in specific gravity which are the result of this, play an important part, inasmuch as they strike a continual balance between the forces tending to raise and depress the fish's body. The laws according to which the swim-bladder plays its part in a fish are in general the same as those which hold good for the Cartesian diver, and these laws are now considerably cleared up by the speaker's researches.

CONTENTS.

THURSDAY, FEBRUARY 20, 1890.

THE PHYSICS AND CHEMISTRY OF THE "CHALLENGER" EXPEDITION.

Report on the Scientific Results of the Exploring Voyage of H.M.S. "Challenger," 1873-76. Physics and Chemistry, Vol. II. (Published by Order of Her Majesty's Government, 1889.)

THE second volume of the Report on the Physics and Chemistry of the *Challenger* Expedition has been published, and contains matter of very great interest.

The first paper is on the compressibility of water, by Prof. Tait. He has used Amagat's "manomètre à pistons libres."

"The principle on which the instrument works is the same as that of the Manomètre Desgoffes—a sort of inverse of that of the well-known Bramah Press. In the British instrument, pistons of very different sectional area are subjected to the same pressure (that of one mass of liquid), and the total thrust on each is, of course, proportional to its section. In the French instrument, the pistons are subjected to *equal* total thrusts, being exposed respectively to fluid pressures which are inversely proportional to their sections. The British instrument is employed for the purpose of overcoming great resistances by means of moderate forces; the French, for that of measuring great pressures in terms of small and easily measurable pressures."

By means of the instrument from his description of which the above is an extract (p. 21), Prof. Tait has determined the compressibilities of cistern water, sea water, and solutions of common salt up to pressures of 450 atmospheres, and for a range of temperature extending from 0° to 15° C. The results may be briefly summed up as follows.

The average compressibility of fresh water at 0° C. and at low pressures is 520×10^{-7} per atmosphere. The compressibility is a minimum at 60° C. Both the compressibility and the temperature at which the minimum occurs are lowered by pressure. The average compressibility for a pressure of 456·9 atmospheres is 478×10^{-7} per atmosphere, and the temperature of minimum compressibility is about 30° C. The average compressibility of sea water is about 0·92 of that of fresh water. The point of minimum compressibility is about 56° C. at atmospheric pressure.

At 0° C. the average compressibility of water per atmosphere may be expressed by the formula $0·00186/(36 + p)$, where p is the pressure in tons per square inch. The compressibility of solutions of NaCl, containing s parts of salt to 100 of water, is given by the formula

$$0·00186/(36 + p + s).$$

The depth of a sea about six miles deep is reduced by 620 feet by compression. If the ocean were incompressible, the level of the surface would be 116 feet higher than it is at present, and about two million square miles of land would be submerged. Finally, the maximum density-point of water is lowered by about 3° C. by an additional pressure of 150 atmospheres, and the temperature of maximum density coincides with the freezing-point at $-2°·4$ C. under a pressure of 2·14 tons per square inch.

It will be seen from this brief recapitulation of his results that Prof. Tait has carried through a very difficult research with success, and has made substantial additions to our knowledge. It may therefore appear ungracious to criticize points which do not touch the essence of the investigation, but it is impossible to read the Report without feeling that, in some respects, it falls short of the standard of classical perfection which ought to be attained in papers published at the national expense to illustrate a great national research.

In the first place, the C.G.S. system is entirely ignored. As the compressibilities are measured *per atmosphere*, this is, so far, not of importance; but in the formulæ quoted above, which express the compressibility per atmosphere, terms occur in which the pressures are measured in tons per square inch. The units are thus mixed, and though the requisite data for conversion into atmospheres are supplied, there is no doubt that foreigners will have some difficulty in interpreting the results.

Again, though we cannot but admire the scrupulous honesty with which he tells the tale, some annoyance may justly be felt that a paper should go forth to the world in a publication intended to mark the highest level to which British science has attained, marred by the confession that the author—who deservedly holds a place in the very foremost ranks of British physicists—had never heard of Van der Waals' work on the continuity of the liquid and gaseous states till the end of the year 1888.

Van der Waals' investigation was published in Dutch in 1873. In spite of the disadvantage due to the language in which it was written, its importance was at once recognized. Clerk-Maxwell gave a long account of it in NATURE in 1874 (vol. x. p. 477). He returned to the subject in a lecture delivered before the Chemical Society on February 18, 1875, and reported in full in NATURE (vol. xi. p. 357). After indicating what he considered to be the weak points of Van der Waals' theory, he added that nevertheless "his attack on this difficult question is so able and so brave, that it cannot fail to give a notable impulse to molecular science. It has certainly directed the attention of more than one inquirer to the study of the Low-Dutch language in which it is written." Maxwell again referred to Van der Waals in his articles on "Atom" and "Capillary Action," published in the "Encyclopædia Britannica" in 1875 and 1876. So important was the theory considered, that, although it was then four years old, twelve pages were devoted to it in the first number of the "Beiblätter" to *Poggendorff's Annalen* (1877). O. E. Meyer discussed it in his "Kinetische Theorie der Gase" in the same year. It is described in modern German text-books, such as Rühlmann's "Handbuch der Mechanischen Wärmetheorie," and Winkelmann's edition of Graham-Otto's "Lehrbuch der Chemie," both published in 1885. It was translated in full into German by Dr. Roth in 1881, and an English translation by Prof. Threlfall, of the University of Sydney, is about to be published by the Physical Society of London.

In spite of all this, the author of the Report we are discussing informs us, in an addendum dated August 8, 1888, that only a few days before he had been told by a visitor to his laboratory "that one of Van der Waals' papers (he did not know which, but thought it was a recent one)

contains an elaborate study of the molecular pressure in fluids"; and a few lines further down he refers to "Van der Waals' memoir 'On the Continuity of the Gaseous and Liquid States,' which I have just rapidly perused in a German translation."

In view of the fact that Prof. Tait published a book on "Heat" in 1884, these statements are so astonishing that his interview with the visitor from whom he heard of Van der Waals can only be described, in the words of Mr. Montague Tigg when he discovered that Martin Chuzzlewit was in the next box in the pawn-shop, as "one of the most tremendous meetings in Ancient or Modern History."

Other indications of a lack of acquaintance with what has been done by others are not wanting. Taking $p(v - a) =$ constant, as the equation to the isothermal of a gas, and assuming that it applies approximately to a liquid, the author concludes "that water [at 0° C.] can be compressed to somewhat less than three-fourths of its original bulk, but not further." He adds that "the whole of this speculation is of the roughest character," but makes no reference to the converging lines of evidence which indicate that liquids could be compressed to from 0·2 to 0·3 of their bulk at ordinary temperatures and pressures. The numbers which lead to this conclusion are frequently in good accord, whether they are deduced from direct observation on the specific inductive capacities or the refractive indices of the liquids themselves, or from those of their vapours, or from the molecular volumes of the elements of which they are composed. The latter, however, as calculated in the few cases he discussed from Van der Waals' theory, are larger, except in the case of hydrogen, than the corresponding numbers obtained from optical or electrical measurements. Van der Waals did not deal with water-vapour, but if we use the molecular volumes for H_2 and air obtained by means of O. Meyer's modification of his theory, and take the molecular volumes of air and O_2 as identical (an assumption which will certainly make the result too large), we obtain the following values:—

Volume of the Matter in the Unit Volume of Water under Standard Conditions.

Deduced from observations on the refractive index of liquid water (L. Lorentz)	0·2061.
Deduced from observations on the refractive index of water-vapour (L. Lorentz)	0·2068.
Deduced from the molecular volumes of H_2 and O_2 obtained from refractive index or specific inductive capacity	0·23.
Deduced from the molecular volumes of H_2 and air given by Van der Waals' theory	0·33.

Prof. Tait's value is 0·717. It is certainly unfortunate that a number so widely divergent from the results of a whole literature of optical, electrical, and thermal researches should be published in a *Challenger* Report without any reference to the discrepancy. It is still more unfortunate that in discussing the theory on which this result is based the opinion should be registered that "the quantity a [in the formula $p(v - a) =$ constant] obviously denotes the ultimate volume" (p. 48). This was published sixteen years after Van der Waals had given reasons for believing that a (or, as he calls it, b) is four times the ultimate volume, and twelve years after O. Meyer had argued that the multiplier ought to be increased to $4\sqrt{2}$. The best theories on the subject are no doubt tentative, their agreement with facts is imperfect, but it is established beyond the possibility of doubt that the constant in question need not have the meaning which is here said to be obvious.

Two papers in which the compressibilities of solutions of NaCl are discussed had appeared in *Wiedemann's Annalen* some little time before the conclusion of Prof. Tait's work. Röntgen and Schneider (*Wied. Ann.*, xxix. 165, 1886) determined the relative compressibilities of water and of a number of different salt-solutions, and Schumann (*Wied. Ann.*, xxxi. 14, May 1887) gave absolute measures. Both researches were carried on at low pressures only, but they are interesting in their relation to Prof. Tait's conclusions, inasmuch as his compressibilities at low pressures are obtained (as he fully explains) by an extrapolation, and it is therefore desirable to compare them with the values given by direct observation.

In the following table the compressibilities obtained by Schumann for solutions containing given percentages of NaCl (*i.e.* parts of salt to 100 of solution) are compared with the values deduced from Prof. Tait's formula:—

Percentage.	Compressibility per atmosphere × 10^6.	
	Schumann.	Tait.
0	50·3	52·0
5	45·5	45·1
10	39·7	39·5
15	34·8	34·6
20	30·6	30·5
25	25·8	26·8

It is to be observed that the number 50·3 is assumed by Schumann from Grassi, and that it was employed in experiments made with water, for determining the effect of pressure on the internal volume of the piezometers. If it had been replaced by Prof. Tait's value, the close agreement between the results for mean percentages would be destroyed. Schumann also obtains maxima of compressibility for low percentages of certain salts, though he seems very doubtful about the validity of these results. We have no intention of entering into a detailed discussion of his work which certainly appears to require confirmation, but there is no doubt that nobody could have made a critical comparison between his own experiments and those of Schumann so well as Prof. Tait, when he had the whole subject at his fingers' ends. It is thus a real loss to science when a man of his great ability ignores an investigation published nearly a year before the date of his own paper.

The form of the formula given by Prof. Tait for the compressibility of salt-solutions is closely analogous to that deduced from theory by Prof. J. J. Thomson in his "Applications of Dynamics to Physics and Chemistry" (p. 184). He shows that if k' is the compressibility of water, and P is the internal pressure due to the solution of a salt, the compressibility of the solution is $k'/(1 + \mathrm{P}k')$. If then we put $k' = 0{\cdot}00186/(36 + p)$, Prof. Tait's formula for a salt-solution becomes $k'/\left\{1 + k'\frac{s}{0{\cdot}00186}\right\}$, which, since P is proportional to very similar to J. J. Thomson's

expression, and would be identical with it if P = $s/0.00186$ atmospheres. In that case the internal pressure due to the salt in a solution containing 20 parts of salt to 100 of water would be about the same as the internal pressure in pure water as given by Van der Waals. If, however, we attempt to apply van 't Hoff's theory of the pressure due to dissolved substances, we find, as in the examples quoted in the "Applications" (*loc. cit.*), that the observed values of Pk' are many times greater than those given by calculation.

The second Report, by Mr. Buchan, on "Atmospheric Circulation," of which we shall give some account in a future number, is rather a treatise on meteorology than a simple discussion of the *Challenger* observations. All the data, other than those derived from the expedition (which have been previously published), are set forth, and a vast collection of meteorological facts from all parts of the world is utilized.

It would be impossible to attempt to discuss Mr. Buchan's conclusions in detail, but one may be selected as an example. Twenty-six thunderstorms occurred at sea during the voyage, and of these only four took place between 8 a.m. and 10 p.m. Nineteen occurred when the ship was near the land, and these were pretty evenly distributed throughout the twenty-four hours. Over land thunderstorms are most frequent during the day. At sea thunderstorms are nocturnal, and occur chiefly during the morning minimum of pressure.

"Over the land the maximum of thunderstorms occurs during the hours of the day when temperature is the highest, but over the open sea during those hours when temperature is lowest. The great majority of thunderstorms over the land thus occur during the part of the day when the ascensional movement of the air from the heated surface of the ground takes place" (p. 32).

These facts furnish Mr. Buchan with an interesting suggestion as to the cause of these differences:—

"As regards thunderstorms over the land surfaces of the globe, the disturbance of atmospheric equilibrium, resulting in ascending and descending currents, is brought about mainly by the superheating of the surface and thence of the lowermost strata of the air. But as regards the open sea, this mode of disturbing the atmospheric equilibrium cannot take place, inasmuch as the influence of solar radiation is only to raise the temperature of the surface of the sea not more than a degree. Hence it is probable that the disturbance of the equilibrium of the atmosphere, in the case of thunderstorms over the open sea, is brought about by the cooling of the higher strata of the atmosphere by terrestrial radiation" (p. 34).

There can be little doubt that Mr. Murray is right in thinking that Mr. Buchan's Report will be a standard work of reference for many years to come.

The third Report, by Commander Creak, is on the Magnetical Results of the voyage. As the author has himself described the main results of his investigations in the pages of NATURE, it is unnecessary to do more than refer to its most salient features. We have two, and only two criticisms to make. Commander Creak has employed the British unit of force, and his paper will therefore be used with less comfort and ease by most magneticians than if he had employed the C.G.S. system. Perhaps, however, as an Admiralty official he felt bound to adhere to the traditions of his office. Again, we think that he has been rather too modest in the amount of space he has claimed. Like Mr. Buchan, he has used information from many sources which are not, or at all events are not stated to be, generally accessible. These he has employed in determining the rates of secular change during the last 40 years all over the globe. It would have been interesting if means could have been devised for showing not merely the results of this investigation but the data on which they are based. Again, the map in which the direction of motion—eastward or westward—of the north pole of the needle is graphically shown for the period considered would have been more valuable if the magnitudes of the mean annual motion at different places had been added. This has, in fact, been done in a recent German work on the same subject.

But if we are inclined to wish that Commander Creak had claimed a larger share of space and given more details, in what he has done he has gone beyond any previous writer. His work is of the highest importance as introducing a novel view of the causes of secular magnetic change, and in connecting it with certain definite localities.

Mr. Buchan has furnished us with new meteorological maps. Commander Creak has prepared new magnetic maps, which enable us to institute a comparison between the magnetic state of the globe in 1880 and its condition when Sabine portrayed it for an epoch some 40 years earlier. The positions of the magnetic poles and foci of maximum intensity do not appear to have altered. The secular change is associated, not with these, but with four points, towards two of which the north pole of the needle is veering, and from two of which it is apparently being repelled. The points of increasing attraction on the north-seeking pole are to the south of Cape Horn and in the south of China; the foci of diminishing attraction are in the Gulf of Guinea and near the north magnetic pole in Canada. The existence of this last focus is more or less hypothetical, but in the case of the other three the various magnetic elements concur in indicating the same neighbourhood as the centre of change. Thus not only is the secular variation of the declination of opposite signs to the east and west of these points, but the increase of the downward attraction on the north pole of the needle is a maximum near Cape Horn and in China, and a minimum (*i.e.* a maximum decrease) in the Bight of Benin.

Again the annual change of horizontal force is very small near Cape Horn, but it is decreasing in South America, and the rate of decrease is a maximum at a point between Valparaiso and Monte Video. These are precisely the kind of results which would follow from the gradual production of a subsidiary centre of relative attraction on the north-seeking pole of the magnet near Cape Horn. The real existence of the Gulf of Guinea centre is similarly confirmed. Commander Creak cautiously abstains from theorizing on these remarkable facts, but there can be no doubt that he is right in thinking that they must lead us to look for the chief causes of secular variation within the globe rather than in solar or extra-terrestrial influences. His paper will be a point of new departure in the science of terrestrial magnetism.

It will be seen from what has been said that the three Reports which have been discussed are written with a wider scope than the mere discussion of the observations

made during the voyage of the *Challenger*. Prof. Tait's paper has indeed little connection with the work of the Expedition. Mr. Buchan and Commander Creak have worked up an immense amount of matter derived from other sources.

The records of the *Challenger* have not only added facts of great importance to our stock of knowledge; but have been, as it were, nuclei round which a host of other observations have crystallized into orderly arrangement. Each one of the authors has made a step forward. Prof. Tait has extended the range of pressure over which compressibilities have been measured. Mr. Buchan has attacked the diurnal climatology of the ocean. Commander Creak has given a new turn to our ideas on the secular change of terrestrial magnetism. It is only to be regretted that the exclusive use of British systems of measurement, and the other blemishes to which we have felt compelled to refer, give a certain insular appearance and character to a work of world-wide interest.

The Report on the Rock-Specimens collected on Oceanic Islands, by Prof. A. Renard, consists of 180 pages, well illustrated by woodcuts and seven maps, and constitutes a very important part of the petrology of the *Challenger* Expedition. The account of the rocks of St. Paul's from the pen of Prof. Renard has already appeared in Vol. II. (Narrative), Appendix B, of the *Challenger* Reports, and we are glad to learn from the preface to the volume now before us that the "Report on Deep-Sea Deposits" which has been so long looked for by geologists, is to be issued next month.

Mr. Murray is to be congratulated on having secured the services of so able a mineralogist and petrographer as Prof. Renard to describe the rocks brought home by the Expedition. Most of these descriptions have already appeared in the *Bulletin of the Musée Royal d'Histoire Naturelle de Belgique;* but English geologists will be glad to see them collected together and published in their own language, and in a convenient form for reference.

Prof. Renard explains in his opening remarks the grounds for publishing this account of the rock-specimens collected on the oceanic islands by the officers of the *Challenger* Expedition:—

"Mr. Murray had discovered that loose volcanic materials played a very large part in the formation of the deposits of the deep sea, and it was considered desirable to institute a comparison between these and the products of the same origin in volcanic islands situated in or on the borders of the great ocean basins."

It is at the same time admitted, by the editor of the volume, that Prof. Renard's lithological and mineralogical descriptions must be regarded rather as contributions to the geology of the islands visited, than as supplying full and descriptive discussions of the subject.

"The necessities of the voyage, bad weather, or the difficulties of the exploration, prevented, in many cases, the naturalists from passing more than an hour or two on shore; they were thus unable to give any detailed account of the stratigraphical relations, and the collections of hand-specimens were sometimes limited to those rocks situated near the coast."

In the case of Tenerife, of which we have such full descriptions in the writings of Von Fritsch and Reiss, and of Sauer; in that of the Cape de Verde Islands, the rocks of which have been carefully studied by Dölter; and of Fernando Noronha, which has been surveyed and its rocks admirably described by Profs. Branner and Williams, it is obvious that the description of the specimens placed in the hands of Prof. Renard can only be regarded as supplementary to the fuller and more comprehensive accounts of the geology of the islands which we already possess. But in the case of some of the smaller islands, like Tristan da Cunha, Marion Island, and Heard Island, the notes in the present Report constitute almost the only materials which exist for judging of their geological constitution and structure. In the case of the Island of St. Thomas, in the West Indies; of Kandavu, in Fiji; of the volcano of Goonong Api, in the Banda Islands; of the volcano of Ternate, and of several islands in the Philippine Group, Prof. Renard has taken the opportunity afforded to him by the receipt of interesting specimens casually collected, to discuss points of considerable mineralogical and geological interest.

Quite apart from their connection with certain localities, these very careful notes of Prof. Renard on peculiarities exhibited by rock-forming minerals are of much value to geologists; and so also are the series of analyses of these rock-specimens, made, evidently with great care, by Dr. Klement.

So many of the islands visited by the *Challenger* were previously touched at by the *Beagle*, on board of which Charles Darwin was acting as naturalist, that it is impossible to avoid comparing the work before us with that author's classical memoir, "Geological Observations on the Volcanic Islands," which was published in 1844 and re-issued in 1876. In spite of the improvements of our petrographical methods during the half-century, which has witnessed the application of the microscope to the study of rocks, it is very interesting to see how often observations made by Darwin, aided by that great pioneer in crystallographic research, Prof. W. H. Miller of Cambridge, are confirmed by the painstaking labours of Prof. Renard. There is, perhaps, some danger, at the present day, that the facilities afforded for the microscopic study of rocks, by the aid of transparent sections, should lead geologists and mineralogists to despise, or to regard as of small value, the observations made without such aid. To those who entertain such an idea, it will be instructive to see how Darwin and Miller by the aid of pocket-lens, knife-blade, and magnet, were often able to form an appreciation of the mineralogical constitution of rocks, which has been very largely confirmed by the application of the more refined methods of the present day.

The discussion of great geological problems, which, as treated by Darwin in 1844, contributed so largely to the interest excited by his book, have of course not come within the scope of the work undertaken by Prof. Renard. The particular varieties of volcanic rocks in Ascension, which Darwin found to illustrate in so striking a manner the origin of foliation in the crystalline schists, do not seem to have been among those collected by the officers of the *Challenger*. But as an important contribution to micropetrography, the work of Prof. Renard is of the highest value, as might indeed have been anticipated from the well-proved skill and acumen of the author in this interesting branch of scientific research.

THE HUMAN FOOT.

The Human Foot: its Form and Structure, Functions and Clothing. By Thos. S. Ellis. (London: J. and A. Churchill, 1889.)

THIS book is an endeavour on the part of a practical surgeon to explain the mechanical construction of the human foot, and from this basis to show the principles on which boots and shoes ought to be constructed. Although written in a popular form, and intended for the instruction of the public, it is treated in a scientific spirit by one who is competent, on the ground of anatomical knowledge, to discuss the subject. Mr. Ellis was led to give special attention to the mechanism of the foot owing to one of his feet having been accidentally injured; and his recovery from lameness was due to the independent study which he was obliged to give to the structure of the foot in relation to its functions.

The earlier pages of the book are occupied by a short but clearly-written description of the form of the foot, and of so much of its anatomy as is needed to explain its mechanism. In the course of this description the author points out that the two feet are to be considered together, not as if they were two independent pedestals, or plinths, supporting the lower limbs and body, but as the two halves of one pedestal or plinth, the divisions of which are separated from each other. He recognizes the inner margin of the foot in its front or expanded part as forming a straight line, whilst the outer margin forms a bold curve, and acts as a sort of buttress to the main structure of the foot. The inner margin also is elevated to form the arch of the instep. He refers to Prof. Meyer's well-known line continued backwards from the mid-line of the great toe through a central point of the heel which follows the line of the long flexor of the great toe, and states that this line corresponds with the highest part of the ridge on the dorsum or upper surface of the foot, which indicates the course of the long extensor of the great toe.

The importance of the great toe in the construction of the foot is dwelt upon by Mr. Ellis. He shows that, when the foot is used as the basis from which the body is to be propelled forwards in the act of progression, the great toe leaves its fellows and passes towards the mesial plane between the two feet, but that it is not bent in so doing. On the other hand, the smaller toes, whilst being pressed against the ground, become bent, and the phalangeal joints are lifted upwards.

The relative length of the great and second toes is also discussed. As is well known, in many of the statues of ancient art the second toe is modelled somewhat longer than the great toe, but as a rule in nature itself the great toe is the longer. Exceptions, however, occasionally occur. The writer of this notice has now before him the casts of two well-formed feet, from a man and a woman, in both of which the second toe projects beyond the great toe. He has also in his possession casts of the feet of several of the aborigines of Australia, taken under the superintendence of Prof. Anderson Stuart, of the University of Sydney, in which interesting variations in the relative length of these toes may be seen. In a man and one woman the great toe is longer than the second; in another woman the second toe in the right foot is longer than the first, but in the left foot the opposite is the case. In an Australian boy, aged 4, in the right foot the great toe is slightly the longer, but in the left foot the second toe has the advantage. In none of these Australians had the feet ever worn shoes, so that the variation in the length of these toes is natural, and not produced by artificial means. It would appear, therefore—as was shown several years ago by Prof. Ecker, of Freiburg, and by a writer in NATURE, to be the case in the hand with the ring and index finger—that variations in relative length may occur, not only in different individuals, but in opposite limbs in the same person.

The author then discusses the movements at the joints of the foot and the action of the muscles; more especially when the heel is raised and the foot rests on tip-toe as in the movements of progression. He regards the long flexor of the hallux as exercising a bow-string or tie-rod influence, bracing up the arch and diminishing the distance between the heel and the great toe. Hence the exercise of dancing is one of the most important means of promoting and maintaining the strength of the foot. As regards the act of walking, Mr. Ellis contends that what he calls the "four-square position," in which the inner borders of the great toes are retained almost parallel to each other, is that which is most conducive to steady and continuous progression, for the joints and muscles of the foot obtain through it momentary rest in the intervals between the steps. He condemns the military position, with the toes turned outwards, both in standing and walking, as much more fatiguing, by keeping the muscles and joints in a constant strain. The condition of "flat-foot" ought never to arise if the tie-rod action of the long flexor muscles of the toes be sufficiently exercised by frequent springing of the foot to tip-toe, such as takes place in the act of dancing.

The author applies the anatomical principles which he has expounded to the construction of stockings and shoes. He holds that quite as much mischief is done to the feet by wearing ill-made socks as badly-shaped shoes. He considers that a stocking with a separate stall for the great toe is always desirable, but that a straight inside line is imperative. To obtain a properly fitting boot it is necessary, in addition to the measures of length and girth, to have the contour lines of the foot, and to obtain these the author has devised a foot-stand or pedistat, a description and figure of which are given in the book. From these measures a last can be made which conforms to the shape of the foot throughout as it stands on a level surface.

We recommend the perusal of this book to all who are interested in the mechanism of the foot, and in obtaining for it well-fitting socks and shoes; and we do so with the more confidence as the author had obviously passed through a painful experience before he had satisfied himself of the principles which ought to be attended to in the construction of its clothing.

OUR BOOK SHELF.

Das australische Florenelement in Europa. Von Dr. Constantin Freiherr von Ettingshausen. Pp. 10. Tab. I. (Graz: Leuschner and Lubensky, 1890.)

THIS is a defence of the identification of fossil plants from the Tertiary beds of Europe, chiefly from Austria and

Hungary, with existing Australian genera. Baron Ettingshausen himself is largely responsible for these identifications, which have been questioned "by certain critics insufficiently acquainted with the subject." He claims that he was supported in his views by such eminent palæontologists as Franz Unger and Oswald Heer. It is now some years since Unger published his sensational "Neuholland in Europa." In this little work almost every one of a set of Eocene fossil plants is identified with some essentially Australian genus, and often, we should add, on the very slenderest of material. The late Mr. G. Bentham, who, as is well known, handled and described every Australian plant of which specimens had been collected up to his time, disputed the correctness of the identifications, and endeavoured to prove that the remains might well be those of genera still found in the northern hemisphere; yet Baron Ettingshausen gives us to understand that Mr. Bentham confirmed his determination of a European fossil leaf as belonging to the genus *Dryandra*.

Quite recently the Marquis de Saporta has attacked Baron Ettingshausen's position, and the present pamphlet may be regarded as a reply. The author concludes with the statement that, to prevent misunderstanding, he wishes it to be known that any objections or criticisms will meet with no response from him, because he is convinced of the accuracy of his "facts," and his time is too valuable to enter upon superfluous discussion. Without discussing his "facts" one by one, and without actually denying their accuracy, we may say that the illustrations given are by no means convincing, as most botanists who have worked many years in herbaria on plants from all parts of the world, we believe, will agree. Few persons probably have paid so much attention to the venation and forms of leaves as Baron Ettingshausen, yet we find none of his determinations absolutely beyond doubt. So far as we are aware, not a single fruit of *Eucalyptus* or of the assumed *Proteaceæ* has been discovered in the European Tertiary formations. As to his leaves of *Eucalyptus*, they might be matched in the genus *Eugenia*, and we see no reason why any of the others are necessarily remains of species of Australian genera. W. B. H.

Is the Copernican System of Astronomy True? By W. S. Cassedy. (Standard Publishing Co., Kittanning, Pa., 1888.)

AN astronomer nowadays would find it a hard task to bring forth any facts which would throw doubt upon the truth of the Copernican theory, but it appears that there are still people amongst us who are bold enough to attack the strongholds of astronomy. Such attempts are always hopeless failures, and the one under notice is no exception. It is, indeed, doubtful whether the author knows what is meant by the Copernican system, for he goes so far as to suggest that the known diameter of the earth's orbit (assuming that it exists) should be used as a base-line for determining the distance of the sun! He also states that he has "found by experiment" that similar right-angled triangles have sides proportionate in length, though it is only fair to say that he is aware of the existence of the first book of Euclid, if not of the sixth.

We have already said enough to show that the book need not be considered seriously; but we cannot refrain from stating that the author, by sighting the sun along straight-edges at the equinoxes, has found that "the distance of the sun from the surface of the earth, at 40° N., is one million miles (p. 49)." This result is about as near the mark as could be expected from the method employed.

Naturalistic Photography. By P. H. Emerson, B.A., M.B. (London: Sampson Low, Marston, Searle, and Rivington, 1890.)

THE quick call for a second edition of this work indicates the approval with which it has been received, and we may safely say there is not a better or more instructive book on the art principles of photography than the one before us. Dr. Emerson is a photographer of the first rank, his artistic compositions are everywhere admired, and the energetic manner with which many of the old and cherished ideas of the ordinary photographer are attacked and others established makes it very manifest that he only writes what he knows to be true. The literary style of the book is excellent, and the exposition has the merit of being strikingly original; it should, therefore, be studied by every photographer, both amateur and professional, who desires to excel in his art.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Acquired Characters and Congenital Variation.

BEYOND this letter I cannot pursue my interpolated adversary, Mr. Dyer.

The syllogisms which he attributes to me are entirely his own. I willingly admit, therefore, that they are as ingeniously bad as they can well be.

I will now state shortly what my position was, and is:—

(1) The assumed antithesis between "acquired characters" and "congenital variation" has arisen out of the cult of Darwin as opposed to Lamarck.

(2) The theory of Lamarck fails, in my opinion, as much as the theory of Darwin, to give any adequate or satisfying explanation either of the genesis, or of the development, of organic forms.

(3) But the theory of Lamarck is more philosophical than the theory of Darwin, in so far as it seeks for, and specifies, a definite natural cause for the phenomena of variation.

(4) The theory of Darwin is essentially unphilosophical in so far as it ascribes these phenomena to pure accident, or fortuity.

(5) That Darwin himself, at one time, if not always, admitted this idea of fortuity to be a mere provisional resort under the difficulties of ignorance.

(6) That the later worshippers of Darwin depart, in this respect, from their master, and making the weakest part of his system the special object of their worship, have set up Fortuity as their idol.

(7) That it is under the influence of this superstition that they now seek to deny altogether that acquired characters can become congenital.

(8) That this denial is against the most familiar experience of Nature, and especially of artificial selection, which is the antetype and foundation of the whole theory of evolution.

(9) That in all domestic animals, and especially in dogs, we have constant proof that many acquired characters may become congenital.

(10) That it is no answer to this argument to demand proof that the babies of a blacksmith are ever born with the abnormal arm-muscle of their papa.

(11) That in order to avoid and evade the force of innumerable facts proving that many acquired characters may, and do, become hereditary, fortuitists have invented a new verbal definition of what they mean by "acquired."

(12) That this definition is full of ambiguities and assumptions, concealed under plausible words, but the object of which is to limit the meaning of "acquired characters" to gross, visible, palpable changes affecting single individuals, and which the analogies of Nature do not lead us to expect or to suppose can be repeated in a single generation, even if a tendency to their development is really implanted in the race.

(13) That, still farther to render impossible the proof they demand, our fortuitists affix to their definition of the word "acquired," conditions which beg the whole question in dispute. Not only must the new characters be gross, palpable, visible—cases of "hypertrophy," of "extension," or of "thickening,"—but also they must be "obviously due to the direct physical action of the environment on the body of the individual." This is a condition which is irrational. It excludes

all those fine, invisible "molecular" changes, through which Nature habitually works, and it ascribes to mere outward and mechanical agencies, effects which, alone, we have no reason to suppose they ever can produce.

On the question of "prophetic germs," Mr. Dyer challenged me to produce a single case of organs useless now, but in course of preparation for future use. I replied by referring him to this phenomenon as universal throughout Nature in the life-history of every individual organism; and I also referred him to the well-known idea of Darwinian embryology which establishes a close analogy between the laws governing the development of the embryo, and the whole past development of organic life.

Mr. Dyer replies that I ought to have explained this sooner—when challenged to do so by Prof. Ray Lankester—an observation which has nothing to do with the merits of the question. The truth is, I wished to close my dispute with that distinguished Professor, as I now desire to close it with Mr. Dyer, and I was satisfied with an indirect admission that, as regards every individual organism, my assertion could not be contradicted. What this involves, I left, and now leave again, as unexhausted as it is indeed inexhaustible.

In conclusion, I must observe upon the use Mr. Dyer makes of the phrase "*a priori* argument," which he apparently uses not only for all deductive argument, but for all analytical reasoning. When he says he "has not an *a priori* mind," he really means that he is indisposed to all analysis. This is a very common attitude even with many able and distinguished men—especially when they are devoted to a system, and are the disciples of some prophet, whose words and phrases they gulp and swallow whole. It is an attitude which has its use; but it is not one to boast of. Mr. Dyer's declaration that "the questions at issue with regard to evolution are now, I believe, thoroughly understood by biologists" is the most astonishing utterance I have ever heard or read coming from a scientific man. Discussion with him is useless. He and his friends know all about it. How life began, and how it grew from more to more—the whole secret of creation—"an open scroll, before them lies." I am happy to think that I am not the only searcher—by many thousands—whose pens Mr. Dyer must intervene to stop. There is a great army of us who are conscious above all things of the ignorance of man. ARGYLL.

Kinellan, Murrayfield, N.B.

IN the number for January 16 (p. 247) Mr. Thiselton Dyer observes that "there are many readers of NATURE who, while taking a general interest in the problems raised by Darwinism, have not followed all that has been written about it." For the benefit of such persons he gives an interesting explanation of Darwin's views on several important points.

I have not read *all* that has been written, but all, I think, that has ever appeared in the pages of NATURE, and with the result that I am more and more convinced of the inadequacy of the Darwinian theory to account for the origin of species. Natural selection is a *vera causa*, but of very limited operation. The theory of sexual selection but partly removes one serious difficulty not of the first magnitude.

I find Darwinians—not Darwin—very ready to insinuate or assert that an unwillingness to adopt their views, on the part of persons who believe in a supernatural revelation, arises from theological prejudice, which hinders them from listening to the voice of reason. I think there is some prejudice on both sides. For myself, fully believing in a Supreme Designer, I am perfectly and most fearlessly willing that "the attempt at mechanical explanation" should be carried as far as possible, well knowing that "a final universal cause" cannot possibly be disproved or reasonably denied. And Darwinism is committed to no such denial.

We have our choice between two alternatives. Life on our globe had a beginning; and its cause was certainly not mechanical or natural,—for reasons not theological, but strictly scientific, in the technical sense of the word. For, as the laws of Nature operate uniformly, if life had ever commenced spontaneously, it must of natural necessity do so again and again, since it would be most absurd to suppose that only during some previous state of the earth's surface did matter exist in such a condition as to be capable of conversion into living things. If life had ever arisen mechanically, it would require a miracle to *prevent* repetitions of the process.

We have, then, to take our choice between supposing with Darwinians that the life-producing power acted once for all, and supposing that it has acted repeatedly and continuously, in more ways than one. I see no theological, and, let me say, no Scriptural, objection to either. Let it be believed willingly, if good reasons can be given, that all life began with a single germ which could not only produce its like—which is wonderful enough—but which even contained in itself such amazing potentialities that it could become, and has become, the parent of every form of life, sentient or non-sentient, that has ever appeared on our globe.

To me this seems scientifically improbable. For why should the power, whether acting intelligently, or, if anyone prefers it, without intelligence, create one germ only? Why not millions? And if of one kind, why not of many? And if single organisms, why not organisms connected with one another, even in highly complex structures? And why act once only? Why not start non-sentient life at one time, sentient at another? For do not sentient things need a separate germ? I take leave to think so. But be this as it may, they are as much in advance of the non-sentient, however much alike those germs we know of may appear to be, as the non-sentient are of inanimate matter.

The other alternative supposition is that the life-producing power, instead of acting once only, and then subsiding into its primæval torpor, continues to act. That, as it once acted upon inanimate matter, not robbing it of anything, but rather, while availing itself of its properties, conferring upon it new powers, so it has acted since upon living things, ever producing out of the old new and higher forms of life; availing itself of all existing faculties of living things, but while allowing them to achieve all that they can, still moulding fresh forms, and conferring higher faculties. To suppose this, is only to suppose that the action of the life-producing power, since life began, has been analogous to what we know was its action in producing life. It is hardly to be supposed that the production of one marvellous germ has exhausted all its energy.

Yet, if the Darwinian theory can enable us to dispense with the aid of this power, let it do so. Let reason prevail.

Darwinians offer, as an adequate explanation of the formation of new species from the older, that this development comes about simply through natural selection—through the survival of the fittest of favourable variations.

"The origin of any species," says Mr. Thiselton Dyer, "lies firstly in the occurrence, and secondly in the selection and preservation, of a particular variation." But surely a particular variation alone—that is, such as can be brought about, as we know from experience, in a single generation—does not sufficiently differentiate one species from another. Short-horned cattle, for instance, are not a new species, nor would they deserve to be so termed if it should eventually happen that all other varieties of horned cattle became extinct. In the great majority of cases, at all events, there must be *more than one* particular variation, before we can recognize a specific difference. Species have become what they are by the *combination*, in one organism, of many particular variations, each well suited to the rest. No particular variation could make of another ruminant a giraffe. What we want, and what seems to be wanting in the Darwinian theory, is a satisfactory hypothesis to explain the *concurrence* of many particular variations, by the co-existence of which in one structure the new species is constituted. Variations, or "fluctuations," as Mr. Thiselton Dyer has happily termed them, will not account for this. Between some species there may be merely slight and single differences; but Nature can show us much more than this. We often find a complicated apparatus formed by the concurrence in one individual of many particulars of structure combining to produce an effect wholly peculiar.

Take the following instance, or rather group of instances. There are venomous serpents, of many species and in many lands, which differ most widely from the non-venomous kinds, from which, or from the ancestors of which, they are generally believed to have been derived. In these we find, to begin with, teeth which have undergone strange modifications. They are needle-like in shape. They are not fixed in the jaw. They occupy a very prominent position. They have minute perforations, terminating near, but not precisely at, the point. They have muscles by which they may be recurved, so that their points may be directed towards the throat. They have hollows in which to lie. They have muscles by which, on occasions, they may be projected beyond the mouth. Besides all this poison-secreting glands, and poison-bags, and channels of com-

munication with the perforations in the teeth. Further still, a special instinct leading the snake to make use of this wonderful weapon of offence, and suitable nerves to regulate its complicated action.

Now, unless all these numerous variations—and they might fairly be multiplied by subdivision—had in the first instance appeared simultaneously in one individual, and unless all had been duly connected, the whole apparatus would have been useless, and there would have been nothing of which natural selection could avail itself. Useful intermediate forms there can be none. A rifle is a more formidable weapon than a lance or dart, but of what use would be a thing half-way between the two? The venom-discharging apparatus has in it no part which could possibly be dispensed with.

To give one more instance. The tongue of the woodpecker is moved forwards in a singular way; not simply, as usual, by a muscle and sinew in front of the base of the tongue, but by a sinew terminating in a loop, through which passes another sinew from behind the tongue which, doubling through the loop, is attached to the base of the tongue. By this means, when the muscle is contracted, the tongue is drawn forward with a double velocity, which is to this bird specially useful. Now, it is impossible for any ingenuity to devise an action intermediate between this and the usual simple pull in respect of utility or complexity. But there is much more here than "a particular variation." The first woodpecker that possessed this structure must have had it in complete order, for otherwise the tongue would not move at all. In that woodpecker it must have commenced to exist in a rudimentary form before birth, in a germ possessing novel powers.

And here I must ask, How is it that anyone questions the Duke of Argyll's statement that "all organs do actually pass through rudimentary stages in which actual use is impossible"? Is it not precisely this which is implied in the Darwinian statement that "from the variable constitution of the ovum probably arises the varying structure of the organism developed from it"? What was afterwards developed was at first rudimentary, and useless. This is equally true of the whole organism—say of the serpent, or of the bird—and of the entirely novel and complicated apparatus found in them.

To call the apparatus in either serpent or bird "a particular variation" would be to give up the whole case for Darwinism. A wonderful *combination of many* particular variations has to be accounted for; and, so far as I can see, Darwinism utterly fails to account for it. There are thousands of cases presenting the same difficulty.

There are simpler cases of specific change, in which the concurrence, the simultaneous appearance, of many slight and particular variations is not indispensable, but only their succession in due order in the course of many generations. Here, there is some room for the theory. Thus perhaps, possibly, we might get a giraffe. But I prefer a theory which, if true at all, accounts as readily for the most complicated apparatus as for the simplest forms of living things. R. COURTENAY.

Hotel Faraglioni, Capri, January 31.

PROBABLY many readers of the recent discussion on the transmission of acquired characters will regret that a more definite conclusion has not been arrived at. This is probably due to the fact that the premises now in our possession do not admit of a definite answer yet being given. Those who assume that there is no evidence in favour of the transmission of acquired characters are mostly, I presume, supporters of "the continuity of the germ-plasm" theory of Weismann. Almost everyone admits that individuals may and do acquire certain characters due to change in environment, use, disuse, &c.; but while many maintain that these characters are transmitted to offspring, others deny that such is the case, or think that the evidence is insufficient. In supporting "the continuity of the germ-plasm" theory it is impossible to suppose that the germ-plasm is continued from one generation to another like a portion of entailed property. For each individual gives off thousands of ova or spermatozoa as the case may be, only a very few of which go to produce new individuals; therefore there is a dissipation of "germ-plasm,"—that is to say, in the germinal cells of mammals of to-day there cannot be any of the identical "germ-plasm" which existed in their remote invertebrate ancestors ages ago. For all this dissipation there must be some constructive process, otherwise the germ-plasm would come to an end.

From whence is derived this constructive material? Clearly from the exterior, for a fertilized ovum obtains material from without to admit of growth and elaboration. The constructive material, then, which the "germ-plasm" obtains—to admit of its liberal dissemination each generation—is derived from the external world, *viâ* the organism with which it is incorporated, or indeed of which it forms a part. Seeing, then, that the organism—from which this germinal matter is derived—can acquire characters—that is, undergo certain definite changes in response to altered conditions—then it seems reasonable to suppose that that part of it which ultimately finds its way to the germ-cells, is also modified during its transmission, and will therefore have more or less effect upon the forthcoming generation. But how much variation is due to the above cause, and how much to the almost infinitely various possible combinations of the two unlike germinal elements, it is impossible to say.

J. COWPER.

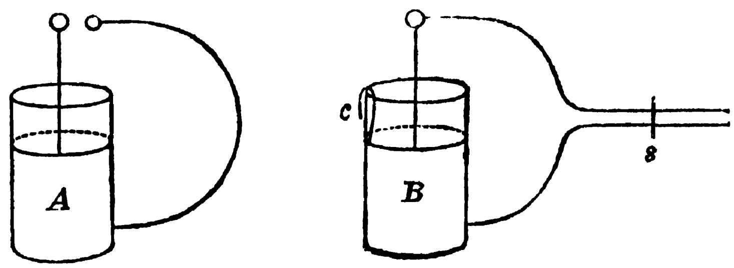
Easy Lecture Experiment in Electric Resonance.

AN experiment, exhibited by me in its early stages at the Royal Institution a year ago, and since shown here in various forms, on the overflow of one Leyden jar by the impulses accumulated from a similar jar discharging in its neighbourhood, is so simple an illustration of electric resonance, and so easily repeated by anyone, that I write to describe it.

Two similar Leyden jars are joined up to similar fairly large loops of wire, one of the circuits having a spark-gap with knobs included, the other being completely metallic, but of an adjustable length.

The jar of this latter circuit has also a strip of tinfoil pasted over its lip so as to provide an overflow path complete with the exception of an air-chink, *c*. It is important that this overflow path be practically devoid of self-induction. A jar already perforated could be well utilized for the purpose.

Then if the two circuits face each other at a reasonable distance, and if the slider, *s*, is properly adjusted, every discharge of A causes B to overflow. A slight shift of the slider puts them out of tune.



Instead of thus adjusting by variable self-induction, my assistant, Mr. Robinson, has made a slight modification by using a condenser of variable capacity, consisting of two glass tubes coated with tinfoil, one sliding into the other, and joined by a flexible loop of wire; an easy overflow from one coat to the other being likewise provided. On making this loop face the discharging circuit of an ordinary Voss machine with customary small jars *in situ*, bright sparks at the overflow gap occur whenever the common machine sparks are taken, provided the sliding condenser be adjusted to the right capacity by trial.

There is little or no advantage in using long primary sparks; the vibrations are steadier and more definite with short ones. It is needless to point out that the 2 jars constitute respectively a Hertz oscillator and receiver, but fair precision of timing is more needed with these large capacities than with mere spheres or discs, because the radiation lasts longer and there are more impulses to accumulate. Hence actual resonance as distinguished from the effect of a violent solitary wave is better marked. Moreover, the sparks are bright enough to be easily seen by a large audience. OLIVER J. LODGE.

University College, Liverpool.

African Monkeys in the West Indies.

WITH reference to the note in NATURE of February 13 (p. 349), on the occurrence of an Old-World monkey in Barbados, I may point out that the same West African monkey (*Cercopithecus callitrichus*) has also been introduced and is now found wild in St. Kitts (cf. Sclater, P.Z.S., 1866, p. 79). It likewise

occurs in Nevis, whence the Zoological Society received living specimens (presented by Mr. Graham Briggs) in 1870.

The only West Indian island in which Quadrumana of the *American* type occurs is Trinidad, which was, doubtless, formerly part of the mainland of South America.

3 Hanover Square, W., February 17. P. L. SCLATER.

Galls.

I HAD not intended to take any further part in this correspondence; but the interesting suggestion which has now been made upon the subject by Mr. T. D. A. Cockerell (NATURE, Feb. 13, p. 344) induces me to withdraw the sentences that he quotes from my previous letters, to the effect that it seems impossible to imagine any way in which galls can be attributed to natural selection acting on the plants *directly*. In my own consideration of the matter this seemed "obvious," and therefore my motive in taking up the difficulty as presented by Mr. Mivart was that of "asking whether anybody else had a better explanation to offer" than the one which my letter suggested—viz. "that natural selection may operate on the plants *indirectly through the insects*," by always selecting those insects the character of whose secretions is such as will best cause the plants to grow the particular kind of morphological abnormality which the larvæ require. Mr. Cockerell, however, has now furnished what seems to me an extremely plausible hypothesis, showing that there is a way in which it is quite conceivable that the growth of galls may be an actual benefit to the plants, and therefore that natural selection may act directly on the plants themselves in evolving these sometimes highly specialized structures for the use of their parasites. Mr. Cockerell informs me in a private communication that he has been verifying this hypothesis by observations in detail; but whether or not he will be able to establish it, I think at any rate he has done good service in thus suggesting another possibility.

On the other hand, I cannot see that Mr. Ainslie Hollis has helped us at all (NATURE, January 23, p. 272). For he merely enunciates the truism that trees which were not endowed with sufficient "developmental vigour" adequately to resist the attacks of gall-making insects "would doubtless have long ago succumbed in a struggle for existence." And this truism he appears to suppose furnishes an explanation of how "natural selection, operating in the ordinary manner," has produced galls for the exclusive benefit of the insects. But it is obvious that the more detrimental the growth of galls has proved to trees, the less reason there must have been for natural selection, "operating in the ordinary manner," to have developed these often highly specialized structures for the benefit of parasites.

London, February 13. GEORGE J. ROMANES.

The Supposed Earthquakes at Chelmsford on January 7.

NATURE for January 16 (p. 256) reprints from the *Essex County Chronicle* a short account of two supposed earthquake-shocks felt at and near Chelmsford on January 7, at 12.30 and 1.25 p.m. Being engaged in the study of British earthquakes, I made inquiries in the district referred to, and the result of these is to show that the shocks were almost certainly due to the firing of unusually heavy guns at Woolwich. It may be worth while to state the evidence for this conclusion somewhat fully, as it will be difficult to obtain it in after years.

(1) I applied to the authorities at Woolwich and Shoeburyness as to the nature of the firing on January 7. At the latter place, the only practice was from 9-inch and 10-inch guns, the maximum charge used was 70 pounds of powder, and therefore not capable of producing the shocks felt at Chelmsford. At Woolwich, however, the 110-ton gun, "*the heaviest in H.M. service*," was fired at the times mentioned.

(2) *Form of the Disturbed Area.*—The only accounts I have as yet received are from the following places: Great Warley (near Romford), Brentwood, Epping, Ingatestone, on the road between Ongar and Fyfield, Roxwell, Chelmsford, Chignall St. James, and Chipping Hill (Witham); which are respectively at about 6, 12½, 14, 16, 16, 21, 24, 24, and 32 miles distance from Woolwich. Referring to a map of Essex, it will be seen that these places all lie close to a line drawn from Woolwich in a north-easterly direction; with the exception of Epping, the direction of which is about north by east from Woolwich. According to the *Times* weather report of January 8, southerly and south-westerly breezes prevailed very generally throughout the kingdom on the previous day.

(3) *Nature of the Shock.*—In four cases, the shock was in the first instance attributed to the firing of heavy guns. If there was any vibration of the earth, it must have been very slight, and the following descriptions seem to leave little doubt that the rattling of windows noticed was due to an air-wave.

Great Warley—The shock "broke a pane of glass 4 feet × 2 feet on my job."

Brentwood—"The shocks commenced as a low rumble, increasing till the doors shook and rattled, as though the rumbling was followed by a bang or explosion."

Between Ongar and Fyfield (the observer driving)—"The ground felt as if it were sinking," and there was "a rumbling noise something like guns in the distance."

Roxwell—The sound "exactly resembled the report of the big guns at Shoebury, but was far louder than we usually hear them."

Chelmsford (the observer walking)—There was "a noise as of a very heavy weight being rolled across the floor of the room of the house to the south of him, which he was passing."

Chignall St. James—"The shock was extremely slight, but there was a most pronounced concussion in the air which made a sound on the windows as if a person had thumped the centre of the window frame with the soft part of his hand. There was no tremulous motion felt."

Witham—The observer "heard a strange rumbling sound which seemed to slightly deafen him, but he felt no vibration of the earth."

That the disturbances recorded had only one origin is, I think, evident, (1) from the decrease in intensity (roughly speaking) as the distance from Woolwich increases, and (2) from there being no considerable gap between the places of observation. Records from the immediate neighbourhood of Woolwich could hardly be expected, as there they would naturally be attributed to their proper source.

I am indebted to the editor of the *Essex County Chronicle* for inserting a letter asking for observations on the shocks, and to several gentlemen for the courtesy and kindness with which they replied to this letter and to other inquiries that I made in the surrounding district. CHARLES DAVISON.

38 Charlotte Road, Birmingham, February 13.

Shining Night-Clouds.

IN July last, on a fine night, about 8 p.m. (two hours after sunset), I noticed a fleecy cloud lit up by a yellowish light, directly over the back of a range of hills due west from this place. As it did not move, it struck my attention, and I observed that what little wind there was carried the few floating clouds north-east to south-west. I continued to watch the cloud, which covered say 4° or 5°, until 11 p.m., and concluded that as in that direction lay the Puracé volcano, about 40 miles away, the light and cloud probably came from it. But I made inquiries by telegraph, and found that no eruption had taken place in the Puracé, which has been quiet now for many years. I regret, seeing now that the subject is interesting, that I did not observe more carefully. I may add that in the direction of the cloud no prairie or forest fire could have occurred to account for it. ROBERT B. WHITE.

A Greenish Meteor.

TO-NIGHT (Jan. 30), at 8.15 p.m., I saw a meteor which, notwithstanding a bright moon, shone out exceedingly brightly, exceeding any star. It appeared to travel south, for about 10°, vanishing about 15° above the horizon. Its colour differed from that of any meteor I have seen before, being pale green or greenish. T. D. A. COCKERELL.

West Cliff, Custer Co., Colorado, January 30.

THE MOLECULAR STABILITY OF METALS, PARTICULARLY OF IRON AND STEEL.

(1) ALLOW me to add some words relative to the very timely lecture on the hardening and tempering of steel, recently published by Prof. Roberts-Austen

(NATURE, xli. pp. 11, 42). I desire, in the first place, to point out the bearing of the singular minimum of the viscosity of hot iron (*loc. cit.*, p. 34) on the interpretation given of Maxwell's theory of viscosity (*Phil. Mag.* (5), xxvi. pp. 183, 397, 1888; xxvii. p. 155, 1889). When iron passes through Barrett's temperature of recalescence, its molecular condition is for an instant almost chaotic. This has now been abundantly proved (cf. John Hopkinson, Phil. Trans., London, clxxx. p. 443, 1889, where the literature may be found; cf. Osmond, below). The number of unstable configurations, or, more clearly, the number of configurations made unstable because they are built up of disintegrating molecules, is therefore at a maximum. It follows that the viscosity of the metal must pass through a minimum. Physically considered, the case is entirely analogous to that of a glass-hard steel rod suddenly exposed to 300°. If all the molecules passed from Osmond's β state to his α state together, the iron or steel would necessarily be liquid. This extreme possibility is, however, at variance with the well-known principles of chemical kinetics. The ratio of stable to unstable configurations cannot at any instant be zero. Hence the minimum viscosity in question, however relatively low, may yet be large in value as compared with the liquid state.

(2) My second point has reference to the function of carbon in steel. It is not to be understood that we ignore the importance of the changes of carburation produced by tempering steel. To explain the varied physical phenomena which accompany temper, it is sufficient to recognize some *special* instability in the tempered metal. This is given by the carbide configuration, and the physical explanations in question may be made without specifying its nature further. Hence the permissibility of the purely physical considerations.

On the other hand, it is indeed surprising that, on the part of engineers and chemists, the important subject of temper has been but inadequately dealt with, as Prof. Austen justly remarks. Sir Frederick Bramwell (cf. NATURE, xxxviii. p. 440), in his inaugural address at Bath, in 1888, dwelt at some length on the subject of temper. The question is again touched upon by Mr. Anderson at the Newcastle meeting of the British Association. Neither of these gentlemen, however, really shows forth the gist of the matter. Indeed, even in Ostwald's massive "Lehrbuch der Allgemeinen Chemie" (Leipzig, W. Engelmann, 1887), full of examples as it is, bearing on all points of chemical physics, the frequent and exceptionally important case of tempered steel is altogether absent. And yet the chemical interpretation to be given to the phenomena of temper seems to be closely at hand. Dr. Strouhal and I (*Wied. Ann*, xi. p. 390, 1880; Bulletin U.S. Geol. Survey, No. 14, chap. ii., 1885) showed that, by the process of hardening, the electrical resistance of steel may be increased by more than three times its value for the soft metal. If the hard rod is now softened, the resistance again decreases by an amount depending on the temperature to which the hard metal is exposed and on the time of such exposure, in a way which, throughout the whole research, is beautifully sharp and characteristic. Eventually, the relatively low resistance of soft steel is again reached. Now suppose the carbon molecule of steel to be dissolved in the metal, forming an alloy of Matthiessen's Class II. Seeing that the quantity of carbon contained is not large, the electrical resistance of hard steel is at once an expression of its chemical composition, structurally unknown though it be. Hence in the electrical diagram of the phenomena of temper constructed by Dr. Strouhal and myself, the time variations of resistance of hard steel at any given temperature may be interpreted as a case of Wilhelmy's (*Pogg. Ann.*, lxxxi., pp. 413, 499, 1850) rate of chemical reaction (*Reactionsgeschwindigkeit*), and expressed in accordance with his well-known exponential law. This indeed is the character of the observed time curves. Hence also the full diagram of the phenomena of temper, considered both in their variation with time and with temperature, is available for the elucidation of most points relative to the effect of temperature on rate of chemical reaction.[1]

(3) A further remark may be made relative to Osmond's (*Annales des Mines*, July–August, 1888, pp. 6–7; *Mém. de l'Artillerie de la Marine*, Paris, 1888, p. 4) iron of the α and the β type. The assertion that mere strain partly changes α into β iron is in conformity with the viscous behaviour of the metal. For it appears that the effect of any mechanical strain as well as of temper, is marked decrease of the viscosity of the metal. Osmond's theory, however, appears to explain too much. Since most metals can be similarly hardened by straining, it would follow that there should be α and β varieties in all these cases, even though a molecular change corresponding to Gore's phenomenon in iron has only in a few instances been observed (iron, nickel, platinum-iridium alloy). I believe, however, that there is reason to be urged even in favour of this extreme view.[2] The ion theory of metallic conductivity is fast gaining ground.

J. J. Thomson states it in his well-known book ("Applications of Dynamics," p. 296). Giese (*Wied. Ann.*, xxxvii. p. 576, 1889) has outlined an ion theory of electric conduction, uniformly applicable to metals, electrolytes, and gases. It seems to me, if a preliminary hypothesis be made relative to the evolution of a magnetic field out of an electric field; if advantage be taken of the spiral distribution of points which frequently results from the symmetrical interpenetration of two congruent Bravais systems;[3] if, finally, in metals, the function performed by a bodily transfer of ions can also be performed by an exchange of the charges of charged atoms (Giese, indirectly Helmholtz), that the possibility of an ion theory of magnetism may be suspected. Quite apart from the influence of a field, the conditions of exceptionally close approach favourable to the transfer of charges from atom to atom, are given by the distribution of the heat agitation in the metal.

(4) I will close this note by some remarks on the change of the character of diffusion when occurring in solids. Studying the coloured oxide coats on iron, Dr. Strouhal and I (Bull. U.S.G.S., No. 27, p. 51, 1886) pointed out that the outer surface of the film is oxidized as highly as possible in air; and that the inner surface of the film, continually in contact with iron, is reduced as far as possible. This distribution of the degree of oxidation along the normal to the layer, is equivalent to a force in virtue of which oxide is moved through the layer, from its external surface to its internal surface. The formation of an oxide coat is thus a case of diffusion. Conformably with this view, the film, during its formation, behaves like an electrolyte, as was pointed out by Franz, Gaugain, and Jenkin, and more recently by Bidwell and by S. P. Thompson.

We then adverted to the crucial difference between diffusion in solids and diffusion in liquids, inasmuch as in the former case (solids) diffusion demonstrably *ceases* after a certain small thickness is permeated. The limit thickness of the film is reached asymptotically, through infinite time. It has a definite value for each temperature, increasing as temperature increases. In the light of other evidence since gained, this explanation is substantiated. The formation of the

[1] An ulterior consideration presents itself here relative to an extension of the theory of Arrhenius (*Wied. Ann.*, iv. p. 391, 1878) to metallic conductivity. Arrhenius and Ostwald find in the maximum of electrolytic conductivity a measure of rate of reaction. I must pass over this question here, since it is without immediate bearing on the text.

[2] I have spent much time in endeavouring to throw light on this question, and will indicate the results later. My methods were (1) to find the effect of mechanical strain on the carburation of steel; (2) to find the effect of strain on the rate of solution; (3) to find the hydro-electric effect of stretching.

[3] A good account of the relations of the Bravais and the Sohncke system is given by H. A. Miers, in NATURE, xxxix. p. 277.

oxide coat is a case of solid diffusion, and as such it bears the same relation to the diffusion of liquids, that the viscosity of solids bears to the viscosity of liquids. The two phases (solid, liquid) of each phenomenon are to be correlated in ways essentially alike. The available stress, as compared with the available instability at a given temperature, determines the time character of the result.

CARL BARUS.

Physical Laboratory, U.S. Geological Survey, Washington, D.C.

CHRISTOFORUS HENRICUS DIEDERICUS BUYS BALLOT.

BUYS BALLOT was born on October 10, 1817, at Kloetinge in Zealand; was a student in arts and the natural sciences at the University of Utrecht, where he first became Lector of Physics and Chemistry in 1844, and then successively Professor of Mathematics in 1847, and of Experimental Physics in 1870, which latter chair he ceased to hold in November 1887 on completing his fortieth year as Professor. He was appointed Director of the Royal Meteorological Institute of the Netherlands in 1854, and held this position with great ability and distinction till his death on Monday, the 3rd of the present month.

His first contribution to science was a paper on a chemical subject in 1842, this being a science of which he was Lector at the time; but soon thereafter he turned his attention to meteorology, which he emphatically made the business of his life. The following are among the earlier of his papers on the subject, and they are, it will be seen, very significant of his future work:—"On the Influence of the Rotation of the Sun on the Temperature of our Atmosphere," in 1846; "On the Importance in Meteorology of Deviations from the Mean States of the Atmosphere," in 1850; "Results of the Observations of 1849 and 1850 in different places in Holland," in 1851; and "On Synchronous Representations of Weather Phenomena," in 1854.

In these early times of meteorology, when instruments and modes of observing still greatly needed the guiding hand of science towards the founding of international meteorology, Dr. Buys Ballot was wisely led to attempt the construction of no general isobaric and isothermal maps in investigating storms and other weather phenomena, but contented himself in investigating weather disturbances by representing them over the surface of Europe by means of deviations from the means, or averages, of the places represented. In this mode of working he made several of his more important contributions to meteorology, and out of it developed the system of storm warnings he issued for Holland. In this connection his barometric and thermometric means for a very large number of places over Europe will long be a standard work. Of these contributions, unquestionably the most important is that known as BUYS BALLOT'S LAW OF THE WINDS, which states the relation between the direction of the wind and the distribution of atmospheric pressure at the time the wind is blowing. This relation was further developed by Dr. Buchan in 1869, in his paper on the mean pressure of the atmosphere and prevailing winds of the globe, in which it was shown that the prevailing winds of all climates are simply the result of the distribution of pressure.

One of the most exhaustive discussions of the influence of the moon on weather was made by Dr. Ballot. The discussion covered a period of about a century, and he showed that the longer the period the closer do the cases for or against any such influence approach equality. Subsequent to Maury, Dr. Ballot was one of the earlier and most energetic and successful workers in maritime meteorology, and his meteorological charts of the routes of Dutch ships over the great oceans is a standard work. Dr. Ballot also took an active and efficient part in the Meteorological Conferences and Congresses held at intervals from 1872 to 1888, which have brought about a greater uniformity in meteorological observations and discussions than previously existed. He was chosen, by the first Congress, President of the Permanent Committee. Among his last works was the proposal of a method of developing and representing the variability of the weather and climates by the values of the deviations of the daily observations from the averages, irrespective of sign.

The great merits of his indefatigable services to science, but more particularly to meteorology, were recognized by his being made LL.D. of Edinburgh University, Knight of the Order of the Netherland Lion, Commander of the Order of Franz Joseph of Austria, and of St. James of the Sword of Portugal, and Knight of second class of the Prussian Order of the Crown. But above all, his ever readiness in every degree to oblige, the genial sunshine of his face, and his lovableness, make his death to be felt by many of us as a sharp personal bereavement.

NOTES.

ON Tuesday evening the Cambridge University Natural Science Club and the Master of Downing (Dr. Alex. Hill) gave a *conversazione* at Downing Lodge, at which 260 guests, including many distinguished residents and non-residents, were present. The several scientific professors were very liberal in lending the treasures from their museums, and as this is the first entertainment of the kind which has been given in Cambridge, many objects of great historic interest, such as Babbage's calculating machine, Cavendish's apparatus, &c., were exhibited. Artificial silk was spun, quartz filaments drawn, smokeless gunpowder and other scientific novelties shown. One of the most interesting exhibits was a series of Egyptian heads unwrapped from their mummy cloths, and artfully "restored" by Prof. Macalister. A very attractive feature of the entertainment was an address by Dr. Lauder Brunton, who had much that was interesting to say about his recent experiences in India. Mr. Gardiner illustrated the dispersion of seeds by the aid of the limelight and boxes of seeds of various kinds suspended from the ceiling.

THE annual general meeting of the Geological Society of London will be held to-morrow (Friday) at 3 o'clock, and the Fellows and their friends will dine together at the Criterion Restaurant at 7.30 p.m.

BEFORE the next ordinary meeting of the Royal Microscopical Society, it will have moved its quarters from the rooms hitherto occcupied by it in King's College, which are now required for the purposes of the College, to 20 Hanover Square. The ordinary meetings will in future be held on the third instead of the second Wednesday in the month, and the annual meeting in January instead of February. The Quekett Microscopical Club has also transferred its place of meeting to 20 Hanover Square since the commencement of the year.

WE regret to have to record the death of Sir Robert Kane, F.R.S. He died after a short illness on Sunday, the 16th inst., at his residence in Dublin.

THE fine buildings of the University of Toronto were almost wholly destroyed by fire last Friday. The flames were unfortunately fanned by a strong wind, and the fire spread so rapidly that hardly anything could be saved. A small number of specimens in the museum, and some of the scientific apparatus, were brought out by students, but they were mostly broken while

being removed. The Canadians are justly proud of the University of Toronto, and will no doubt provide for it even more splendid buildings than those which are now in ruins.

SIGNOR SELLA's views of the Caucasus have been on exhibition in the Royal Geographical Society's map-room since Friday last, and will continue to be exhibited till the close of the month.

WE print elsewhere Prof. David P. Todd's record of work done by the U.S. Scientific Expedition to West Africa, 1889, of which he was director. This is one of several bulletins printed on board the U.S.S. *Pensacola*.

IN the engineering notes from North-West India, of *Engineering* of the 14th inst., we find a most interesting account of the testing of the Chenab Bridge, near Mooltan. This bridge consists partly of seventeen spans of 200 feet, which are of mild steel throughout. These trusses are of the Whipple-Murphy type, with raking heel posts; the ties are at an angle of 45°, and consequently the depth is a tenth of the span. In previous girders of this type, made in iron, the deflection under full loads was usually less than 0·0004 of the span, while here $1\frac{1}{2}$ inch, equal to 0·0006, obtains throughout, and in each case the observed permanent set is less than $\frac{1}{8}$ inch in the whole thirty-four girders in the viaduct. *Engineering* observes that "there is thus no question of bad workmanship either in the pieces sent out from home or in the erection at site, and it is very clear that steel structures, especially when so light as these spans, which only weigh, with corrugated floor and all bearing and expansion gear, 220 tons each, are necessarily more sensitive than those of iron."

THE new number of the *Internationales Archiv für Ethnographie* (Band ii. Heft vi.) opens with a valuable paper, by Prof. G. Schlegel, of Leyden, on Siamese and Chinese-Siamese coins. This contribution is illustrated by a coloured plate. Of the other papers, the most important is an account of the Nanga of the Fiji Islands, by Mr. Adolph B. Joske, Fiji. These remarkable stone inclosures, now ruined, were first brought to the notice of anthropologists by the Rev. Lorimer Fison, of the Australasian Wesleyan Mission. Three of them have been visited by Mr. Joske, and he is thus enabled to give the plan of an inclosure drawn from his own measurements. His paper has been edited by Baron Anatole von Hügel, who adds instructive notes. In another paper, Prof. Giglioli gives an interesting account of a remarkable stone axe and stone chisel in use among the Chamacocos of South-East Bolivia.

WE are glad to observe that in the Ceylon estimates for the current year provision is made for an increased vote of Rs. 10,000 for archæological purposes. Sir Arthur Gordon, in explaining the vote, said, "It is proposed to make some systematic examination of the interesting remains at Sigiri, and to commence on a modest scale, before the rapidly disappearing monuments of the past have altogether perished, a species of archæological survey resembling that carried on in India. Such an examination should be completed in about three years, and the vote is proposed to cover the salary and travelling expenses, for 1890, of the officer selected for the purpose."

A LARGE and rich collection of specimens of amber, illustrating all the varieties found in the amber district of North Germany, has lately been sent to the New York School of Mines by one of its earliest graduates, Mr. H. A. Demelli, now a resident of Berlin. At a recent meeting of the New York Academy of Sciences, this collection was examined with great interest by the members, and Dr. Newberry, the President, read an instructive paper on amber. After the reading of the paper, Dr. N. L. Britton spoke of the occasional occurrence of amber in New Jersey, in connection with the lignites so abundant in the Cretaceous and Eocene beds; and Mr. George F. Kunz exhibited several specimens of American amber, one of which —from Mexico—excited much admiration. Mr. Kunz said that during the last fifteen or twenty years travellers had occasionally brought specimens of a very remarkable amber from some locality in Southern Mexico. The only thing known about this amber is that it is taken to the coast by natives, who report that it occurs in the interior so plentifully, and in such large pieces, that they use it for making fires. It is of a rich, deep golden yellow, and, when viewed in different positions, it exhibits a remarkably green fluorescence, like that of certain petroleums. It is perfectly transparent, and, according to Mr. Kunz, even more beautiful than the famous so-called opalescent or green amber found at Catania, Sicily.

A FRESH illustration of the way in which foreign plants may become "weeds" under new and favourable conditions is afforded by *Melilotus alba* in the Western States of America. It was introduced a few years ago as a garden-plant, and has spread so rapidly in the rich bottom-lands along the Missouri River that, according to *Garden and Forest*, it is fast driving out the sunflower and other native weeds. It is commonly called "Bokhara clover."

AT the meeting of the Scientific Committee of the Royal Horticultural Society, on February 11, Dr. Oliver and Prof. Scott presented an interim report on the investigations undertaken by them respecting the effects of London fogs on plants under glass. Specimens of orchids affected by fog had been received from Messrs. Veitch and Son, Chelsea; and of tomato plants from the superintendent of the Royal Horticultural Society's gardens at Chiswick. On the suggestion of the chairman, it was decided that the chemical constituents of London fog should be investigated, and that the exciting causes of the injury to plants should be traced. In order that the work might be carried out under advantageous circumstances, it was resolved that application should be made to the Government Grant Committee of the Royal Society for pecuniary aid.

AT the same meeting of the Royal Horticultural Society's Scientific Committee, Mr. McLachlan drew attention to a disease in sugar-cane at St. Vincent, where in some localities about 25 per cent. of the crop would be lost this year. According to Mr. Herbert Smith, who had examined the canes, a beetle of the family Scolytidæ, and the larva of a moth, were concerned. It is probable that the beetles enter the canes only by the exit holes of the moths, and that the moth is a widely spread species, already known to attack sugar-cane in other countries.

IN the January number of the *American Naturalist* Mr. R. E. C. Stearns begins what promises to be an interesting series of papers on the effects of musical sounds on animals. His first paper deals with "dogs and music." From his friend, Prof. George Davidson, of California, he has received the following instance:—"A small black-and-tan named 'Bessie,' belonging to Mr. A. B. Corson, of North Fifth Street, Philadelphia, will, on hearing 'Shall we meet beyond the river?' sung, throw her head back and set up a most dismal howl, while the tears will run down her cheeks. If the tune is played solemnly on an organ and no word spoken, the same thing will occur; but if any of the words are spoken, with not the slightest musical intonation, she will run to the speaker, and beg and plead in her own way, and do everything but speak, to have it stopped."

THE *Annalen der Hydrographie und Maritimen Meteorologie* for December, published by the German Admiralty, contains an interesting discussion by Dr. W. J. van Bebber, on the dependence of the force of the winds upon the surface over which they blow. It is generally admitted that the winds at sea are, under

similar circumstances, stronger than on land; but actual comparisons, such as the author has undertaken, are not frequently made. He has chosen two stations on the coast—viz. Cherbourg and Hurst Castle—having a different position with regard to the sea, but at which the observations are made under nearly similar conditions. The results of careful comparisons under eight points of the compass, for a period of several years, plainly show that in all months the northerly and north-easterly winds at Cherbourg are considerably stronger than at Hurst Castle, and that the southerly winds at Cherbourg fall considerably short in strength of those at Hurst Castle. The tables show that the strong winds coming from the sea are on an average one degree of Beaufort's scale (1–12) heavier than those coming from the land, while, with lighter or local winds, the difference often amounts to two degrees of the above scale. Information of this kind should be of use to fishermen and others when putting to sea.

M. PLANTAMOUR gives, in a recent number of the *Archives des Sciences*, the results of his eleventh year's observations of periodic movements of the ground, as shown by spirit-levels. It appears that, while in general the east side sinks with lowering of temperature, and rises with a rise, these movements do not always follow with the same rapidity. A sudden change of temperature produces at once a rise or sinking of the east side; but the maxima of the ground-positions rarely coincide with the maximum or minimum of temperature. This eleventh year is exceptional in that the extremes of temperature are but one or two days in advance of those of the movements, whereas in previous years the retardation has been a fortnight to four months behind minimum temperature, and a fortnight to three months behind maximum. In two years (1881 and 1885) the maximum of rise was even four days before the maximum of temperature. Thus, while temperature seems to be the chief cause of the oscillations, some other opposing cause must be at work. M. Plantamour compared the eleven years' mean effects with the variations in solar intensity, but failed to detect any relation.

CARL HESS, the German naturalist, has proved by minute microscopical investigation that the eye of the mole is perfectly capable of seeing, and that it is not short-sighted, as another naturalist (Kadyi) would have us believe. Hess maintains that, in spite of its minute dimensions,—1 millimetre by 0·9 millimetre—the eye of this little creature possesses all the necessary properties for seeing that the most highly-developed eye does; that it is, indeed, as well suited for seeing as the eye of any other mammal, and that in the matter of refraction it does not differ from the normal eye. In order to bear out the theory of short-sightedness, the physiological reason was adduced that in its subterranean runs the mole is accustomed to see things at close distances, and that its eye had become gradually suited to near objects. But to this Hess objects that the mole when under ground most probably makes no use of his eyes at all, as it would be impossible to see anything owing to the absence of light, but that when he comes to the surface, and especially when he is swimming, he does use his eyes. In order to accomplish this, he only has to alter the erect position of the hairs which surround and cover his eyes, and which prevent the entry of dirt when he is under ground, and at the same time to protrude his eyes forward.

IT seems rather strange that, while skins and eggs of the Great Auk are so highly valued, the public rarely hear of Pallas's Cormorant, the extinction of which in the North Pacific corresponds to that of the Great Auk in the North Atlantic. Only four specimens of Pallas's Cormorant are known to exist in museums; no one possesses its eggs; and no bones were found or preserved until Mr. Leonhard Stejneger, of the Smithsonian Institution, was so fortunate some years ago as to rescue a few of them. Yet this bird was the largest and handsomest of its tribe. So says Mr. Stejneger in an interesting paper—just issued by the Smithsonian Institution—in which he records how the bones referred to were found by him in 1882 near the north-western extremity of Behring Island. In an appendix to this paper Mr. Stejneger's "find" is fully and exactly described by Mr. Frederic A. Lucas.

WE have received the first two numbers of the *Scottish Journal of Natural History*. This monthly periodical is intended to be mainly a chronicle of the work done by the different Natural History Societies in Scotland; but short papers on subjects connected with Natural History will also be given, and we notice that articles have been promised by well known men of science, including Profs. James Geikie, G. J. Romanes, and many others. At present very few of the Scottish Natural History Societies print Transactions; so there is ample room for the new venture, and we wish it all success. Communications are to be addressed to the Editors, care of the publisher, Mr. W. B. Robinson, 194 Sauchiehall Street, and 105 New City Road, Glasgow.

THE first part of the Memoirs and Proceedings of the Manchester Literary and Philosophical Society for the current session has been issued. It contains a paper by Mr. Charles Bailey, on the discovery near Ribblehead of *Arenaria gothica*, a plant new to Britain, the typical form of which has so far been recorded only for two Swedish localities. The Ribblehead specimens are stated to be more robust than those from Sweden. The issue also includes a paper by Mr. Charles H. Lees on the law of cooling and its bearing on the theory of heat in bars; and the first part of Mr. Faraday's "Selections from the (unpublished) Correspondence of Colonel John Leigh Philips, of Mayfield, Manchester" (1761–1814). The latter includes letters from Dr. Henry Clarke (the mathematician), James Sowerby, and a number of other persons of local eminence during the latter half of the last century.

PROF. WEISMANN requests us to state that in his article on Heredity, printed in NATURE on February 6, the sentence beginning on p. 319, line 38, should have read—"Sir William Thomson, in endeavouring to make clear the dispersion of rays of light by conceiving of a molecule as consisting of hollow spheres enclosed one within the other and in contact with one another through springs, never believed," &c.

TWO gaseous fluorides of carbon, the tetrafluoride, CF_4, and the difluoride, C_2F_4, have been isolated, and form the subject of two simultaneous papers contributed to the current number of the *Comptes rendus*. One of these communications is from M. Moissan, whose energy in this domain of chemistry appears untiring. Unlike chlorine, fluorine directly attacks carbon with varying degrees of energy, according to the form in which the carbon is presented. When a current of pure fluorine is passed over the purest form of lamp-black, which has previously been freed from hydrocarbons by digestion with petroleum and boiling alcohol, combination occurs with such energy that the whole of the finely divided carbon becomes instantly incandescent. The lighter varieties of wood charcoal also take fire spontaneously in fluorine, the gas appearing to be first condensed for a few moments, and then the mass becomes suddenly incandescent and throws off brilliant scintillations. If the density of the charcoal is greater, and there is no loose dust upon its surface, it is necessary to warm it to 50°–100° C. in order to bring about combination and its accompanying incandescence. When once the incandescence is started at any spot it rapidly extends throughout the entire mass. Ferruginous graphite requires to be heated to a temperature just below dull redness, and gas retort carbon to full redness, in order to effect combination, while the diamond may be heated for any length of time over a

Bunsen lamp without any alteration in weight being noticeable. The products of combination are generally gaseous mixtures of CF_4 and probably C_2F_4. When the most readily attacked varieties of carbon are employed, and only in small quantities so as to avoid excess, the gas is almost pure CF_4. Carbon tetrafluoride is a colourless gas, which liquefies under a pressure of five atmospheres at 10° C. It is completely absorbed and decomposed by an alcoholic solution of potash with production of potassium fluoride and carbonate. On decomposing the latter salt with an acid the volume of carbon dioxide liberated is the same as that of the carbon tetrafluoride used. CF_4 is slightly soluble in water, more readily in carbon tetrachloride, alcohol, or benzene. Determinations of its density gave numbers which agreed with the formula CF_4. If excess of carbon is heated to redness in a platinum tube, and fluorine allowed to slowly stream through, another gas is obtained on collecting over water which is not capable of being absorbed by alcoholic potash. This gas liquefies at 10° under a pressure of 19-20 atmospheres. M. Moissan does not seem to have yet determined its composition, but it appears likely to be the C_2F_4 described in the second communication by M. Chabrié. M. Moissan also states that CF_4 may likewise be prepared by passing vapour of carbon tetrachloride over silver fluoride heated to a temperature of 300° C. in a glass or metal tube. M. Chabrié shows that both CF_4 and C_2F_4 may be obtained by heating the corresponding chlorides of carbon with silver fluoride in a sealed tube to 220° C. In an actual experiment 5·1 grams of AgF were heated with 1·55 grams of CCl_4 for two hours, at the end of which time the tube, which itself was but little attacked, was opened, and an almost theoretical yield of CF_4 obtained; the gas was totally absorbed by alcoholic potash in accordance with the equation $CF_4 + 6KOH = K_2CO_3 + 4KF + 3H_2O$. When C_2Cl_4 was used instead of CCl_4, a gas whose density corresponded to the formula C_2F_4 was obtained. The experimental density was 3·43; the calculated value for C_2F_4 is 3·46. The spectra of the two fluorides, according to M. Moissan, exhibit the lines of fluorine very clearly, together with several broad bands, resembling the flutings of carbon.

OUR ASTRONOMICAL COLUMN.

Objects for the Spectroscope.

Sidereal Time at Greenwich at 10 p.m. on February 20 8h. 3m. 7s.

Name.	Mag.	Colour.	R A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 1565	—	—	7 36 25	−14 29
(2) 27 Cancri	6	Yellowish-red.	8 20 39	+13 1
(3) β Cancri	4	Yellow.	8 10 36	+ 9 32
(4) ζ Canis Min. ...	5	White.	7 46 0	+12 3
(5) 26 Pickering ...	Var.	Reddish-yellow.	7 57 2	−12 47
(6) S Cygni	Var.	Reddish.	20 3 14	+57 40

Remarks.

(1) "Planetery nebula; pretty bright, pretty small; extremely little elongated." The spectrum has not yet been recorded.

(2) A star of Group II. Dunér states that the bands are very wide and dark in the red, but weaker in the green and blue. He does not, however, state what bands are present. Observations similar to those already suggested for other stars of the group are required.

(3) This is stated to have a fine spectrum of the solar type by Vogel. The usual differential observations are required.

(4) A star of Group IV. (Vogel). Usual observations required.

(5) This star has a very feeble spectrum of the Group VI. type, which has not yet been fully described.

(6) Although Cygnus is not now in the most convenient position for observations, it may still be observed soon after sunset. The variable, S Cygni, has not yet had its spectrum recorded, and the approaching maximum (February 28) may therefore be taken advantage of. Gore states the period as 323 days, and the range as from 8·8–10·1 at maximum to <13 at minimum. If it has a banded spectrum, as may be expected from the colour, the type of spectrum will probably not be difficult to determine, notwithstanding the faintness of the star.

A. Fowler.

Progress of Astronomy in 1886.—An account of the progress of astronomy in the year 1886, by Prof. Winlock, has been issued from the Smithsonian Institution. Although the record is primarily intended to serve as a series of notes for those who have not access to a large astronomical library, the bibliography will be found useful to the professional astronomer as a reference list of technical papers. A considerable amount of useful information is given in this extract from the Smithsonian Report for 1886–87, the section devoted to reports of Observatories being very complete. A subject-index to the review has been effected by inserting the necessary page references to the bibliography.

The Maximum Light-Intensity of the Solar Spectrum.—We have received from Dr. Mengarini his paper on the above subject (*Untersuchungen zur Naturlehre des Menschen und der Thiere*, xiv. Band, 2 Heft). After reviewing the previous work that has been done on the varying intensity of different parts of the spectrum, the author describes the three methods he used in his researches. The observations led him to conclude that the maximum of light-intensity is subject to variability in position from day to day and hour to hour, just as the maxima of thermal and chemical effects of the spectrum, although the sky be clear and the atmosphere steady. Using a prismatic spectrum, it was found that the maximum light-intensity fluctuated between about λ 564 and D, and, generally speaking, was more pronounced in the morning than in the afternoon. Some observations made at Rome in July 1881, on clear or slightly clouded days, showed that the maximum shifted from λ 564·1 to 584·3.

Spectrum of Borelly's Comet, *g* 1889.—Mr. Backhouse, in a letter to the *Observatory*, notes that he observed the spectrum of this comet with a Browning miniature spectroscope on the 15th and 19th ultimo. The three CO bands were very vividly seen, but no other line; on the former date there was a very faint continuous spectrum, but on the latter only a suspicion of such.

Spectra of δ and μ Centauri.—Prof. Pickering, in a communication to *Astronomische Nachrichten*, No. 2951, records that an examination of the photographs of stellar spectra taken by Mr. S. J. Baily at the Harvard Observatory station, near Closica, Peru, shows that the F line due to hydrogen is bright in the spectra of the stars δ and μ Centauri.

On the Star System ξ Scorpii.—Some elaborate researches into the orbits of the components of this system were given by Dr. Schorr in an inaugural dissertation at Munich University last year. All available measures of position-angle and distance have been brought together and compared with those derivable from the new elements found, making the computation of great value.

GEOGRAPHICAL NOTES.

On Tuesday, Dr. Nansen lectured in Christiania on his plan for a North Pole Expedition. He advocates the employment of a ship built with a special view to strength, having its sides constructed at such an angle that, instead of being crushed by the ice, the vessel would be raised by it. The Expedition, he thinks, should advance through the Behring Straits, where the vessel would be carried northward by a favourable current. At the New Siberian Island the vessel would enter the ice-floes. It would then "proceed towards the North Pole, in which direction the current would probably carry it."

The *Colonies and India* gives the last news from Cooktown relating to Sir William Macgregor's explorations in New Guinea. His project was to ascend the Fly River on another voyage of discovery. It seems that Sir William and his party, in a steam launch, dropped anchor in the river on December 14. The

launch stranded, and fifteen canoes, carrying about 150 natives, bore down upon the explorers and commenced a savage attack. The Governor's party opened fire, and the natives promptly beat a retreat. After about half an hour, however, they returned, bringing a pig as a peace offering. Sir William consequently went 180 miles further up the river, and on his return visited the same people again, to find them quite peaceably inclined. The Governor started again on December 26 to explore higher up the Fly River.

THE Survey Department of Burmah has in preparation a new map containing all the latest information derived from the parties sent out by the Department. A preliminary issue omitting all the mountain ranges has recently been published.

SIGNOR G. B. SACCHIERO, Italian Consul at Rangoon, sends to the *Bollettino* of the Italian Geographical Society for December an interesting notice of the savage Chin tribes who occupy the hilly region in the north of Burma about the headwaters of the Irawady. The collective tribal name is variously written Chin, Kyen, Kiyin, Kachin, Kakyen, &c.; but they call themselves Sihù, and according to Signor Sacchiero they evidently belong to the Burmese branch of the Mongol stock. In the districts brought under British rule many have already adopted the Burmese dress, and these can with difficulty be distinguished from the Burmese themselves. But the language is more allied to that of the widespread Karen race, and the Karen alphabet composed by the American missionaries in Lower Burma is well suited for expressing the sounds of the Chin idiom. The Chins themselves have no knowledge of letters; nor have they made any progress beyond the rudest state of social culture. They still go nearly naked, and the women on arriving at the age of puberty are tattooed all over the face with a black pigment, being thus disfigured for life, either to prevent the Burmese or the neighbouring tribes from kidnapping them, or else to distinguish them from the women captured by the Chins from the surrounding peoples. They marry early, the bride requiring the consent, not of her parents, but of an elder brother, and the husband promising not to beat her too much, nor to cut her hair if she behaves well. The family yields obedience to the father alone, who recognizes no authority except that of the village chief, this authority passing in both cases to the youngest son. The men always carry firearms, and make their own gunpowder, using instead of sulphur a seed called *aunglak*, first roasted, and then pounded up with charcoal and saltpetre, three parts of the two first to twenty of the last, and mixing the whole with alcohol, or tobacco juice. Both sexes smoke little Indian hookahs, and their favourite drink is *khaung*, a kind of beer extracted from fermented rice. They live mainly by the chase, and when a boar, stag, or other big game is captured, there are great rejoicings in the village. The quarry is covered from neck to tail in a red cloth, and presented to the "temple," or abode of the *nat* (spirit); then the "friend of the *nat*" (priest) pronounces a blessing on the successful hunter, after which all join in the feast, with much tamtaming, shouting, drinking, and dancing through the village. When they descend to the plains, the Chins are Buddhists, but in their villages spirit-worshippers. Not only every village and every district, but every person has his special *nat*, mostly a malevolent being who requires to be pacified by propitiatory offerings. The vendetta is a universal institution, feuds being inherited from family to family, from tribe to tribe, and thus leading to constant bloodshed. If a man is drowned, his son reeks vengeance on the water where he perished by piercing it with spears or slashing it about with long knives. Many of the Chins have already tendered their submission to the British authorities, and arrangements are now in progress for extending orderly government over the whole territory.

ON SOME NEEDLESS DIFFICULTIES IN THE STUDY OF NATURAL HISTORY.[1]

A LITTLE while ago I read, in the preface to a work on natural history, that the book was "of little value to the scientific reader, but that its various anecdotes, and its minute detail of observation would be found useful and entertaining."

What, then, may the "scientific reader" be expected to desire? He must be, in my opinion, a most unreasonable man, if he does not thankfully welcome anecdotes of the creatures he wishes to study, when these anecdotes are the result of patient and accurate observation. For it is precisely such information, that is conspicuously absent from many scientific memoirs and monographs; the author generally spending his main space and strength in examining the shape and structure of his animals, and in comparing one with another, but giving the most meagre details of their lives and habits.

Which, then, is the more scientific treatment of a group of animals—that which catalogues, classifies, measures, weighs, counts, and dissects, or that which simply observes and relates? Or, to put it in another way, which is the better thing to do—to treat the animal as a dead specimen, or as a living one?

Merely to state the question is to answer it. It is the living animal that is so intensely interesting, and the main use of the indexing, classifying, measuring, and counting is to enable us to recognize it when alive, and to help us to understand its perplexing actions.

But, it may be objected, that because the study of the living animal is the more interesting, it is not necessarily the more scientific; indeed, that the amount of entertainment, which we may get out of the pursuit of natural history, has nothing to do with the question at all; that by science we mean accurate knowledge presented in the most suitable form; that shape, structure, number, weight, comparison are the fundamental notions, with which sciences of every kind have to deal; and that scientific natural history is more properly that which takes cognizance of a creature's size, form, bodily organs, and relation to other creatures, than that which concerns itself with the animal's disposition and habits.

I can fancy that I already hear some of my audience say: "But why set up any antagonism between these two ways of studying a creature? Both are necessary to its thorough comprehension, and our text-books should contain information of both kinds; we should be told how an animal is made, where it ought to be placed among others of the same group, and also how it lives, and what are its ways."

Precisely; that is just what memoirs and text-books ought to do; but what, too often, they do *not*. We read much of the animal's organs; we see plates showing that its bristles have been counted, and its muscular fibres traced to the last thread; we have the structure of its tissues analyzed to their very elements; we have long discussions on its title to rank with this group or that; and sometimes even disquisitions on the probable form and habits of some extremely remote, but quite hypothetical ancestor—some "archirotator" (to take an instance from my own subject) who is made to degrade in this way, or to advance in that, or who is credited with one organ, or deprived of another, just as the ever-varying necessities of a desperate hypothesis require:—but of the living creature itself, of the way it lives, of the craft with which it secures its prey or outwits its enemies, of the home that it constructs, of its charming confidence or its diabolical temper, of its curious courtship, its droll tricks, its games of play, its fun and spite, of its perplexing stupidity coupled with actions of almost human sagacity—of all this, this which is the real natural history of the animal, we, too often, hear little or nothing. And the reason is obvious, for in many cases the writer has no such information to give; and, even when he has, he is compelled by fashion to give so much space to that which is considered to be the more scientific portion of his subject, that he has scant room for the more interesting. Neither ought we to be surprised if a writer is "gravelled for the lack of matter," when he comes to speak of an animal's life; for the study of the lives of a large majority is a difficult one. It requires not only abundant leisure, but superabundant patience, a residence favourably situated for the pursuit, and an equally favourable condition of things at home. The student, too, must be ready to adopt the inconvenient hours of the creatures that he watches, and be indifferent to the criticisms of those that watch *him*. If his enthusiasm will not carry him, without concern, through dark nights, early mornings, vile weather, fatiguing distances, and caustic chaff, the root of the matter is not in him. Besides, he ought to have a natural aptitude for the pursuit, and know how to look for what he wants to see; or if he does not know, to be able to make a shrewd guess: and, above all, when circumstances are not favourable, to have wit enough to invent some means of making them so. And yet when the place, the man, the animals, and the circumstances all seem to promise a rich harvest of observations, how often it happens that some luckless accident, a snapt twig, a

[1] The Presidential Address to the Royal Microscopical Society, at the annual meeting, on February 12, 1890, by Dr. C. T. Hudson, F.R.S.

lost glass, a hovering kestrel, a sudden gust of wind, a roving dog, or a summer shower, robs the unlucky naturalist of his due; nay, it sometimes happens that, startled by some rare sight, or lost in admiration of it, he himself lets the happy moment slip, and is obliged to be contented with a sketch from memory, when he might have had one from life.

But I have not yet got to the bottom of my budget—the heaviest trouble still remains; and that is, that the result of a day's watching will often go into a few lines, or even into a few words; and so it happens, that the writer of the history of a natural group of animals is too frequently driven to fill up his space with minute analysis of structure, discussions on classification, disputes on the use of obscure organs, or descriptions of trifling varieties; which, exalted to the rank of species, fill his pages with wearisome repetitions; for were he, before he writes his book, to endeavour to make himself acquainted with the habits of all the creatures he describes, his own life-time might be spent in the pursuit.

We will now take a different case, and suppose that many years have been spent in the constant and successful study of the animals themselves; and that the time has come, when the naturalist may write his book, with the hope of treating, with due consideration, the most interesting portion of his subject. He is now beset with a new class of difficulties, and finds that publishers and scientific fashion alike, combine to drive him into the old groove: for the former limit his space, by naturally demurring to a constantly increasing number of plates and an ever lengthening text; while the latter insists so strongly on having a complete record of the structure, and points of difference, of every species, however insignificant, that it is hardly possible to do much more than give that record—a mere dry shuck, emptied of nearly all that makes natural history delightful.

And so we come round again to the point that I have already glanced at, viz. "Ought natural history to be delightful?"

Ought it to be delightful! Say, rather, ought it to exist? What title has the greater part of natural history to any existence but that it charms us? It is true that this study may help—does help many—to worthier conceptions of the unseen, to loftier hopes, to higher praise; that it gives us broader and sounder notions of the possible relation of animals, not only to one another, but also to ourselves; that it provides us with the material for fascinating speculations on the embryology of our passions and mental powers; and that it may even serve to suggest theories of the commencement and end of things, of matter, of life, of mind, and of consciousness—grave questions, scarcely to be dealt with successfully by human faculties, but in a condition to be discussed with infinite relish.

When I speak, then, of the pleasure we derive from the study of natural history, I include these graver and higher pleasures in the word.

Here and there, too, no doubt, the knowledge of the powers and habits of animals is materially useful to us; and, indeed, in the case of some of the minuter organisms, may be of terrible importance; but, in that of the large majority of creatures, we might go out of the world unconscious of their existence (as, indeed, very many people do), and yet, unlike the little jackdaw, not be "a penny the worse." For what is a man the better for studying butterflies, unless he is delighted with their beauty, their structure, and their transformations? Why should he learn anything about wasps and ants, unless their ways give him a thrill of pleasure? What can the living plumes of the rock-zoophytes do for us, but 'witch our eyes with their loveliness, or entrance us with the sight of their tiny fleets of medusa-buds, watery ghostlets, flitting away, laden with the fate of future generations?

When, at dusk, we steal into the woods to hear the nightingale, or watch the night-jar, what more do we hope for than to delight our ears with the notes of the one, or our eyes with the flight of the other? When the microscope dazzles us with the sight of a world, whose inhabitants and their doings surpass the wildest flights of nightmare or fairy tale, do we speculate on what possible service this strange creation may render us? Do we give a thought to the ponderous polysyllables that these mites bear in our upper world, or to their formal marshalling into ranks and companies, which are ever being pulled to pieces, to be again re-arranged? No! it is the living creature itself which chains us to the magic tube. For there we see that the dream of worlds peopled with unimagined forms of life—with sentient beings whose ways are a mystery, and whose thoughts we cannot even guess at—is a reality that lies at our very feet; that the air we breathe, the dust that plagues our nostrils, the water we fear to drink, teem with forms more amazing than any with which our fancy has peopled the distant stars; and that the actions of some of the humblest arouse in us the bewildering suspicion, that, even in these invisible specks, there is a faint foreboding of our own dual nature.

If, then, we make some few exceptions, we are entitled to say that the study of natural history depends for its existence on the pleasure that it gives, and the curiosity that it excites and gratifies: and yet, if this be so, see how cruelly we often treat it. Round its fair domain we try to draw a triple rampart of uncouth words, elaborate, yet ever-changing classifications, and exasperatingly minute subdivisions; and we place these difficulties in the path of those whose advantages are the least, those who have neither the vigorous tastes that enable them to clear such obstacles at a bound, nor the homes whose fortunate position enables them to slip round them. For modern town life forces a constantly increasing number of students to take their natural history from books; and too often these are either expensive volumes beyond their reach, or dismal abridgments, which have shrunk, under examination pressure, till they are little else than a stony compound of the newest classification and the oldest woodcuts.

But the happier country lad wanders among fields and hedges, by moor and river, sea-washed cliff and shore, learning zoology as he learnt his native tongue, not in paradigms and rules, but from Mother Nature's own lips. He knows the birds by their flight, and (still rarer accomplishment) by their cries. He has never heard of the *Œdicnemus crepitans*, the *Charadrius pluvialis*, or the *Squatarola cinerea*, but he can find a plover's nest, and has seen the young brown peewits peering at him from behind their protecting clods. He has watched the cunning flycatcher leaving her obvious, and yet invisible young, in a hole in an old wall, while it carried off the pellets that might have betrayed their presence; and has stood so still to see the male redstart, that a field-mouse has curled itself up on his warm foot and gone to sleep. He gathers the delicate buds of the wild rose, happily ignorant of the forty-odd names under which that luckless plant has been smothered; and if, perchance, his last birthday has been made memorable by the gift of a microscope, before long he will be glorying in the transparent beauties of *Asplanchna*, unaware that he ought to crush his living prize, in order to find out which of some half-dozen equally barbarous names he ought to give it.

The faults, indeed, of scientific names are so glaring, and the subject is altogether so hopeless, that I will not waste either your time or my patience by dilating on it. But, while admitting that distinct creatures must have different names, and very reluctantly admitting that it seems almost impossible to alter the present fashion of giving them, I see no reason why these, as well as the technical names of parts and organs, should not be kept as much as possible in the background, and not suffered to bristle so in every page, that we might almost say with Job, "There are thistles growing instead of wheat, and cockle instead of barley."

We laughed at the droll parody in which the word *change* was defined as "a perichoretical synechy of pamparallagmatic and porroteroporeumatical differentiations and integrations," yet it would not be a difficult matter to point out sentences, in recent works on our favourite pursuits, that would suggest a similar travesty. No doubt, new notions must often be clothed in new language, and the severer studies of embryology and development require a minute precision of statement that leads to the invention of a multitude of new terms. Moreover, the idea that the meaning of these terms should be contained in the names themselves is excellent; but I cannot say that the result is happy—I might almost say that it is repulsive; and if we suffer this language to invade the more popular side of natural history, I fear that we shall only write for one another, and that our scientific treatises will run the risk of being looked at only for their plates, and of being then bound up with the Russian and Hungarian memoirs.

The multiplication of species, too, is a crying evil, and the exasperating alterations of their names, in consequence of changing classifications, is another. The former, of course, is mainly due to the difficulty, no doubt a very great one, of determining what shall be a species, and what a variety. How widely experts may differ on this question, Darwin has shown, by pointing out that, excluding several polymorphic genera and many trifling varieties, nearly two hundred British species, which are generally considered varieties, have all been ranked by

botanists as species; and that one expert has made no fewer than thirty-seven species of one set of forms, which another arranges in three. Besides, even in the cases where successive naturalists have agreed in separating certain forms, and in considering them true species, it happens now and then, as it did to myself, that a chance discovery throws down the barriers, and unites half-a-dozen species into one.

Under these circumstances one would have expected that the tendency would have been to be chary of making new species, and no doubt this is the practice of the more experienced naturalists; but, among the less experienced, there is a bias in the opposite direction; and all of us, I fear, are liable to this bias when we have found something new; for, even if it is somewhat insignificant, we are inclined to say with Touchstone, "A poor thing, sir, but mine own!" Now, were this fault mended, much would be avoided that tends to make monographs both expensive and dull; for, though the needs of science require a minute record of the varieties of form, which are sometimes of high importance from their bearing on scientific theories, yet the description of them, as varieties, may often be dismissed in a line or two, when nothing further is set forth than their points of difference; whereas, if these forms are raised to the rank of species, they are treated with all the spaced-out dignities of titles, lists of synonyms, specific characters, &c., &c., and so take up a great deal of valuable room, weary the student with repetitions, and divert his attention from the typical forms.

But when everything has been done that seems desirable, when names and classification have been made both simple and stable, and the number of species reduced to a minimum, there will still remain the difficulty that monographs must, from the nature of the case, generally be grave, as well as expensive books of reference, rather than pleasant, readable books, within the reach of the majority. I would suggest then, that, if it be possible, each group of animals should be described not only by an all-embracing monograph, to be kept for reference on the shelves of societies like our own, but by a book that would deal only with a moderate number of typical, or very striking forms; that would describe them fully, illustrate them liberally from life, and give an ample account of their lives and habits.

Such a book should give as little of the classification as possible; it should avoid the use of technical terms, and above all, it should be written with the earnest desire of so interesting the reader in the subject, that he should fling it aside, and rush off to find the animals themselves. By this means we should not only get that active army of out-of-door observers, which science so greatly needs; but, by bringing the account of each group into a reasonable compass, we should enable students of natural history to get a fair knowledge of many subjects, and so greatly widen their ideas and multiply their pleasures.

For why should we be content to read only one or two chapters of Nature's book? To be interested in many things—I had almost said in everything—and thus to have unfailing agreeable occupation for our leisure hours, is no bad receipt for happiness. But life is short, and its duties leave scant time for such pursuits; so that to acquire a specialist's knowledge of one subject would often be to exchange the choice things of many subjects for the uninteresting things of one. And how uninteresting many of them are! How is it possible for any human being to take pleasure in being able to distinguish between a dozen similar creatures, that differ from one another in some trifling matter; that have a spike or two more or less on their backs, or a varying number of undulations in the curve of their jaws, or differently set clumps of bristles on their foreheads? Why should we waste our time, and our thoughts, on such matters? The specialist, unfortunately, must know these things, as well as a hundred others equally painful to acquire and to retain, and no doubt he has his reward; but that reward is not the deep delight that is to be found in the varied study of the humbler animals; of those beings "whom we do but see, and as little know their state, or can describe their interests or their destiny, as we can tell of the inhabitants of the sun and moon; . . creatures who are as much strangers to us, as mysterious, as if they were the fabulous, unearthly beings, more powerful than man, yet his slaves, which Eastern superstitions have invented."

Those, then, who are blest with a love of natural history should never dull their keen appreciation of the wonders and beauties of living things, by studying minute specific differences; or by undertaking the uninteresting office of finding and recording animals, that may indeed be rare, but which differ from those already known in points, whose importance is due solely to arbitrary rules of classification.

This eagerness, to find something new, errs not only in wasting time and thought on matters essentially trivial and dull, but in neglecting things of the greatest interest, which are always and everywhere within reach. Take, for instance, the case of *Melicerta ringens*. What is more common, what more lovely, than this well-known creature? And yet how much there remains to be found out about it. No one, for example, has ever had the patience to watch the animal from its birth to its death; to find out its ordinary length of life, the time that it takes to reach its full growth, the period that elapses between its full growth and death, or, indeed, if there be such a period. And yet even these are points which are well worth the settling. For, if *Melicerta* reaches its full growth any considerable time before the termination of its life, it would seem probable that, owing to the constant action of its cilia, it would either raise its tube far above the level of its head, or else be constantly engaged in the absurd performance of making its pellets and then throwing them away. Who has ever found it in such a condition, or seen it so engaged? yet the uninterrupted action of the pellet cup would turn out the six thousand pellets, which form the largest tube that I am acquainted with, in about eight days, and those of an average tube in less than three; while the animal will live (according to Mr. J. Hood)[1] nearly three months in a zoophyte trough, and no doubt much longer in its natural condition. It is true that the creature's industry in tube-making is not continuous. It is often shut up inside its tube, when all ciliary action ceases; and, moreover, when expanded, it may be seen at times to allow the formed pellet to drift away, instead of depositing it; but, allowing for this, there is no little difficulty in understanding how it is that, with so vigorous a piece of mechanism as the pellet-cup, the tube at all ages, except the earliest, so exactly fits the animal. I am aware that it has been stated that the whole of the cilia (including those of the pellet-cup) are under the animal's control, and that their action can be stopped, or even reversed, at pleasure. But this, I think, is an error. Illusory appearances, like those of a turning cog-wheel, may be produced by viewing the ciliary wreath from certain points, and under certain conditions of illumination; and these apparent motions are often reversed, or even stopped, by a slight alteration either in the position of the animal, in the direction of the light, or in the focussing of the objective. When, however, under any circumstances, the cilia themselves are distinctly seen, they are invariably found to be simply moving up and down; now turning sharply towards their base, and now recovering their erect position. Even the undoubtedly real reversal of the revolution of the pellet in its cup, which is constantly taking place, can be easily explained by purely mechanical considerations, and consistently with the continuous up and down motion of the cilia. Moreover, of the actual stoppage of the cilia, in the expanded Rotiferon, I have never seen a single instance. In all cases, on the slightest opening of the corona, the cilia begin to quiver, and they are always in full action, even before the disk is quite expanded; while, should a portion of the coronal disk chance to be torn away, its cilia will continue to beat for some time after its severance: so that there is good reason for believing, that the ciliary action is beyond the animal's control.

It is possible, indeed, that *Melicerta* may continue to grow (as Mr. Hood says that the Floscules appear to do) as long as it lives; or it may adopt the plan of some species of *Œcistes*, which, to prevent themselves from being hampered by their ever-growing tubes, quit their original station at the bottom of the tube, and attach themselves to it above, creeping gradually upwards as the tube lengthens. At any rate it would be interesting and instructive to watch the growth of a *Melicerta*, and the building of its tube, from the animal's birth to its death. An aquarium, in which *Melicerta* would live healthily and breed freely, could easily be contrived, and a little ingenuity would enable the observer to remove any selected individual to a zoophyte trough and back again, without injury; and his trouble perhaps would be further repaid by such a sight as once delighted my eyes at Clifton, where I picked, from one of the tanks of the Zoological Gardens, some *Vallisneria*, whose ribbon-like leaves were literally furred with the yellow-brown tubes of

[1] Mr. Hood, of Dundee, has kept in his troughs *Melicerta ringens* for 79 days, *Limnias ceratophylli* for 83 days, *Cephalosiphon limnias* for 89 days: the *Floscularia* usually lived about 50 days; but *F. Hoodii* died, before maturity, in 16 days.

Melicerta. I coiled one of these round the wall of a deep cell, and thus brought into the field of view, at once, more than a hundred living *Melicertæ* of all ages and sizes, and all with their wheels in vigorous action; a display never to be forgotten.

Such a tank, so stocked and managed, would probably enable a patient and ingenious observer to decide several other points, about which we are, at present, in ignorance: to say whether the same individual always lays eggs of the same kind, or whether it may lay now female eggs, now male, now ephippial eggs; and to say what determines the kind of egg that is to be laid; whether it is the age of the individual, or the supply of food, or temperature, or sexual intercourse that is the potent cause.

It would, too, hardly be possible for the male, to escape the observation of a naturalist, who possessed a tank in which were hundreds of *Melicertæ*: and the male is as yet almost unknown.

Judge Bedwell found in the tubes of the female, in winter, a small Rotiferon resembling the supposed male, that I had seen playing about *M. tubularia*; only the former had a forked foot, and sharp jaws that were at times protruded beyond the coronal disc. Its frequent occurrence in the tubes in various stages of development, and the nonchalance with which the female suffered it to nibble at her ciliary wreath, inclined the observer to conclude, that the animal was the long sought-for male. Unfortunately it was only observed when in motion, so that its internal structure was not made out; and the matter therefore still rests in some doubt.

No doubt it is a strong argument that the female would probably suffer nothing but a male to take such liberties with her; but it would seem, from the following account, that it is possible for such freedoms to be pushed too far.

Mr. W. Dingwall, of Dundee, was on one occasion watching a male Floscule circling giddily round a female, and constantly annoying her by swimming into her fully expanded coronal cup. Again and again she darted back into her tube, only to find her troublesome wooer blocking up her cup, and sadly interfering with, what to a Floscule is, the very serious business of eating—for these animals will often eat more than their own bulk in a few hours. It was clear at last that the lady would not tolerate this persistent interference with her dinner; for when—after waiting, rather a longer time than usual, closed up in her tube—she once more expanded, only to find him once more in his old position, she lost all patience, and effectually put an end to his absurdities, by giving one monstrous gulp, and swallowing her lover. It will not surprise you to hear that he did not agree with her, and that after a short time she gave up all hope of digesting her mate, and shot him out into the open again, along with the entire contents of her crop. He fell a shapeless, motionless lump; the two score and ten minutes of a male Rotiferon's life cut short to five; but, strange to say, in a second or two, first one or two cilia gave a flicker, then a dozen; then its body began to unwrinkle and to plump up; and, at last, the whole corona gave a gay whirl, and the male shot off as vigorous as ever, but no doubt thoroughly cured of its first attachment.

I have taken *Melicerta ringens*, as an example of what yet remains to be done, even with an animal which is as common in a ditch, as a fly is in a house; but almost every other Rotiferon would have done equally well, for there is scarcely a single species, whose life-history has been thoroughly worked out.

To me, natural history in many of its branches seems to resemble a series of old, rich mines, that have been just scratched at by our remote ancestors, and then deserted. Our predecessors did their best with such feeble apparatus as they had; it was not much, perhaps, but it was wonderful that they did it at all with no better appliances; and it irks me to think that we, who are equipped in a way which they could not even dream of, should turn our backs on the treasures lying at our feet, and go off prospecting in new spots, contented too often with a poor result, merely because it is from a new quarter.

Besides, the love of novelty is a force too valuable to be wasted on a mere hunt for new species in any one group of animals, especially unimportant ones. It should rather be used to make us acquainted with the more striking forms of many groups. Let us have no fear of the reproach of superficial knowledge; everyone's knowledge is superficial about almost everything; and even in the case of those few who have thoroughly mastered some one subject, their knowledge of that must have been superficial for a great portion of their time. Indeed, the taunt is absurd. I can imagine that a superficial knowledge of law, or surgery, or navigation may bring a man into trouble; but what possible harm can it do himself, or anyone else, that he is content with knowing five Rotifera instead of five hundred? And yet if any naturalist were to study only *Floscularia*, *Philodina*, *Copeus*, *Brachionus*, and *Pedalion*, it would give him the greatest possible pleasure, as well as an excellent general notion of the whole class. Let any tyro at the seaside watch the ways and growth of a *Plumularia*, or of a rosy feather-star, his knowledge of the groups to which they belong could certainly not be dignified even with the term "superficial"—"linear" or "punctiform" would be more appropriate; but the pleasure, that he would derive from such a study, could not be gauged by counting the number of animals that he had examined. It would depend on the man himself; and might, I should readily imagine, far exceed that derived by the study of a hundred times the number of forms in books; especially when such a study had been undertaken, not from a natural delight in it, but from some irrelevant reason, such as to support a theory, to criticize an opponent, to earn a distinction, or to pass an examination.

In truth that knowledge of any group of animals, which would rightly be called superficial when contrasted with the knowledge of an expert, is often sufficient to give us a satisfactory acquaintance with the most interesting creatures in it; to make us familiar with processes of growth and reproduction too marvellous to be imagined by the wildest fancy; and to unfold to us the lives of creatures who, while possessing bodily frames so unlike our own that we are sometimes at a loss to explain the functions of their parts, yet startle us by a display of emotions and mental glimmerings, that raise a score of disquieting questions.

Moreover, there is another excellent reason why we should not confine our attention to one subject; and that is, that even the most ardent naturalist must weary at times of his special pursuit. Variety is the very salt of life; we all crave for it, and in natural history, at all events, we can easily gratify the craving. If we are tired of ponds and ditches, there are the rock-pools of our south-western shores, and the surface of our autumn seas. A root of oar-weed torn at random from a rocky ledge, an old whelk shell from deep water, a rough stone from low-water mark, the rubbish of the dredge,—each and all will afford us delightful amusement. It is wonderful, too, what prizes lurk in humble things, and how often these fall to beginners. The very first time that I tried skimming the sea with a muslin net, I picked a piece of green seaweed off the muslin, intending to throw it away; but, seeing a little brown spot on it, I dropped the weed (not a square inch) into a bottle of sea-water, instead. At once the brown speck started off and darted wildly round the bottle. It was too small to be made out with the naked eye, but by the time I had brought my lens to bear, it had vanished. I hunted all over the bottle, and could see nothing, neither with the lens nor without it. I was half inclined to throw away the water; but, as I was certain that I had seen something in it two minutes before, I corked up the bottle and took it home. When I next looked at it, there was the little brown creature flying about as wildly as ever. I soon made out, now, that I had caught a very tiny cephalopod—something like an octopus—and with a pipette I fished it out, and dropped it into a glass cell. At least I dropped the water from the pipette into the cell; but the animal itself had vanished again; I could not see it either in the bottle or the cell. I was not going to be tricked again; so I pushed the cell under the microscope, and there was my prize; motionless, but for its panting; and watching me, as it were, up the microscope with its big blue-green eyes. It was almost colourless, and was dotted at wide intervals with very minute black spots, set quincunx fashion—spots absolutely invisible to the sharpest unaided sight.

As I looked it began to blush—to blush faint orange, then deeper orange, then orange-brown; a patch of colour here, another there, now running across one side of the body, now fading away, again to appear on a tentacle; till at last, as it recovered from its alarm, each black spot began to quiver with rapid expansions and contractions, and then to spread out in ever varying tints, till its wavering outlines had met the expansions of its neighbouring spots; and the little creature, regaining its colour and its courage at the same moment, rushed off once more in a headlong course round the cell.

I was the merest beginner when I saw this, but I had the good luck, knowing nothing whatever about it, and never having given the subject a thought, to see, with my own eyes, how effectually cuttlefishes are protected by their loss of colour, and also to see how the loss takes place.

No doubt the sea-side of our south-western coasts—I mean its creeks, not "the thundering shores of Bude and Bos"—is a paradise for microscopists; but there is no need that we should travel so far afield. Our inland woods, our lanes and pastures, will yield to us a thousand beauties and wonders. The scarlet pimpernel will show its glorious stamens, the flowers of the wound-wort glow like a costly exotic; wild mignonette will rival in its fantastic shape the strangest orchid; the humblest grass will lift a tuft of glistening crystals; the birch and salad-burnet shake out their crimson tassels; the Jungermanns will display their mimic volcanoes, the mosses unfold the delicate lacework of their dainty urns. But the time would fail me to name one tithe of those sources of wonder and delight that lie all around us; and most of which, as in the case of the Rotifera, contain numberless points on which we are all happily ignorant, and therefore in the best of all possible conditions for deriving endless pleasure and instruction from them. Besides, my time and your patience must, I think, be drawing to a close; I would then only once more suggest, that we should not only explore for ourselves all these "pastures new"—no matter how imperfectly—but that we should encourage those, who can be our most efficient guides, to indulge us with the main results in the simplest language. Surely one of the most charming subjects, that can interest human beings, admits of being so treated; and there can be no good reason why the Muse of Natural History (for no doubt there is such a Muse) should resemble that curious nymph among the *Oribatidæ*, whom Mr. Michell found lying under the moss of an old tree, half smothered in a heap of her cast-off skins, admirable types of successive classifications, and abandoned nomenclature.

Happily, however, books in such matters are of little importance; and names and classifications of still less: both these latter, indeed, are of ephemeral interest; they are the pride of to-day, and the reproach of to-morrow. It is to the living animals themselves that we must turn, fascinated not only with their beauty and their actions, but with the questions which the contemplation of them perpetually provokes, and very rarely answers.

For, in the long procession of the humbler creatures, who can tell where life first develops into consciousness, and why it does so; where consciousness first stretches beyond the present so as to include the past, and why that happens; or at what point, and why, memory and consciousness themselves are lighted up by the first faint flashes of reason?

We know nothing now of such matters, and probably we never shall know much; but the mere fact that the study of natural history irresistibly draws us to the consideration of these questions, gives to her pleasant features an undoubted dignity, and raises the charming companion of our leisure hours to the rank of an intimate sharer of some of our gravest thoughts.

THE TOTAL ECLIPSE.

THE U.S.S. *Pensacola* arrived at Saint Paul de Loanda on December 6, after a voyage of 51 days from New York, having made the ports of Horta, Fayal, in the Azores, November 2–3; of Saint Vincent, in the Cape Verdes, November 10–12; of Saint George's Parish, Sierra Leone, November 18–20; and of Elmina, on the Gold Coast, November 26–28.

Immediately on landing at Loanda, it was found that the Rio Quanza steamer, sailing bi-weekly for Muxima, had left two days previously, and that recent washouts along the line of the Caminho de Ferro Trans-Africano made it impracticable for the Expedition to reach either Muxima or Cunga early enough to allow sufficient time for mounting and adjusting the instruments for the eclipse.

I therefore at once decided to locate the Expedition at or near Cape Ledo. Mention should be made here of the courteous civilities of His Excellency the Governor of Loanda, for his kindly interest in the Expedition, and the facilities he offered for the prosecution of the various fields of its work.

The *Pensacola* came to anchor alongside H.M.S. *Bramble* in the little bay to the north of Cape Ledo, on the afternoon of Sunday, December 8. The Eclipse Station was selected in a very favourable spot close to the shore cliffs, and the sites of the principal instruments were determined before night.

A week or ten days' hard work sufficed for getting a large amount of the apparatus in readiness for the eclipse. I placed Prof. Bigelow in charge of the direct photoheliograph of nearly 40 feet focal length, and detailed Mr. Davis to assist him. Mr. Jacoby was intrusted with the charge of the time-determinations, and longitude and latitude work. The *Bramble* was at Cape Ledo on a mission like that of the *Pensacola*, and attending upon the English Eclipse Expedition in charge of Mr. A. Taylor, F.R.A.S.; and through the courtesy of her commanding officer, Captain Langdon, R.N., advantage was taken of her run to St. Paul de Loanda and return, December 14–17, to make a chronometric determination of the longitude, by comparison with the time at Loanda as determined by Mr. Preston, who was left there by the Expedition for the gravity and magnetic work. Also, on the *Bramble's* second return to Loanda, on December 23, another comparison was made.

Prof. Abbe was in charge of the meteorological work and of the organization of parties of observers from the ship's company. A large amount of valuable material results from his work.

The mounting and adjustment of the extensive apparatus for the total eclipse, I reserved for myself. A duplex polar axis eleven feet in length had been constructed of six-inch iron tubings, and mounted with great stability. This axis was driven by powerful clock-work of extreme precision, made by Mr. Saegmueller, of Washington. On this single axis was mounted the totality-battery, consisting of 2 Brashear reflecting telescopes of 8 inches diameter, four Clark telescopes of 3½, 5, 7½, and 8 inches aperture, the second being rigged with an eyepiece enlarging the sun's image to a diameter of 4½ inches, the third being used as a high power directing telescope, while the fourth, a photographic doublet with 10 inch back lens, loaned by the Harvard College Observatory, was arranged for a series of twelve exposures, two of which were made through an orthochromatizing screen provided by Mr. Carbutt; two six-inch Dallmeyer rapid rectilinear lenses of 24 and 38 inches focus; one Schroeder triple objective, of 6 inches aperture and 22 inches focus; one Gundlach orthoscope of 3 inches aperture and 21 inches focus; two flint spectroscopes and one quartz spectroscope loaned by Harvard College Observatory; a duplex photometer of 75 inches focus also provided by Prof. Pickering, and his reversing layer spectroscope for photographing a spectrum trail for fifteen seconds both before and after second and third contacts; a 5 inch Ross lens of 42 inch focus; a 4 inch Spencer objective of 36 inch focus, and a 6·4 inch Merz-Clark objective, both rigged with the means of automatic variation of aperture during totality; and lastly, two duplex cameras provided by Dr. Wright of the Sloane Laboratory of Yale University, for photographic record of the polarization of the corona. In all there were 23 objectives and two mirrors, with their axes adjusted into parallelism.

With the exception of the Gundlach camera, which was reserved for a special investigation of the extreme outer corona, all this apparatus was operated automatically, by an adaptation of the pneumatic organ-valve system of Mr. Merritt Gally, of New York. Exposing shutters were opened and closed, sensitised plates were exchanged for others as soon as exposed, and all the mechanical movements were accomplished with entire precision. Also, by employing an ordinary chronograph in conjunction with the valve system, the exact time of beginning and end of each exposure became a matter of accurate record.

All this apparatus was brought into operation during the period of total eclipse, and over 300 exposures were made in a period of 3m. 10sec.; but no photographs of the corona were secured, as the sun was completely obscured by clouds. However, the entire success of the pneumatic movements is a result of no little value in view of eclipse work in the future.

In addition to this, a silver-on-glass mirror, of 20 inch diameter and 75 feet focal length, by Brashear, lent to the Expedition by Prof. Langley, was so mounted as to throw an image of the corona up the cliff and just underneath the sun at the time of totality. At the focus a beautiful 10 inch image of the sun was formed, and 20 × 24 inch plates of the highest sensitiveness were in readiness to record the coronal streamers. This unusual apparatus was also rendered inoperative by clouds.

With the direct photoheliograph, however, very gratifying success was secured. Seventy pictures of the partial phases were made before totality, and forty after. The serious obstacles to the operation of so long a tube were successfully overcome by means of a skeleton mounting, a combined form of an equatorial stand and tripod; and Prof. Bigelow's sand-clock enabled the precise and easy following of the sun. The revolving plate-holder, of 22 inches diameter, actuated automatically by compressed air, in which the principles of the apparatus of the

National Electric Service Company were employed, was a thorough success. Exposures were made at intervals of six seconds.

A few hours before the eclipse came on, the *Pensacola* went out to sea, and stood in the centre of the eclipse-track at the time of totality. Atmospheric conditions were slightly more favourable there than at the main station of the Expedition, and some interesting results were obtained. During totality, however, the clouds were so thick that it is very doubtful whether the true solar corona was seen at all.

The Eclipse Station was completely dismantled by December, 27, and the *Pensacola* left Cape Ledo on the afternoon of the same day.

Returning to Loanda, it was found that two of the three detached parties of the Expedition sent into the interior to observe the eclipse were unsuccessful on account of clouds. The third has not yet been heard from.

DAVID P. TODD.

U.S.S. *Pensacola*, December 31, 1889.

SCIENTIFIC SERIALS.

Rendiconti del Reale Istituto Lombardo, December.—Results obtained from Dr. L. Weigert's therapeutic treatment of pulmonary phthisis, by Prof. A. Visconti. Seven patients in various stages of consumption have been subjected to this treatment for the purpose of testing its efficacy. It consists in administering superheated dry air (150° to 180° C.), which is inhaled through a specially prepared apparatus, for which Dr. Weigert claims that it acts directly on Koch's bacillus of tuberculosis. In the incipient stages of the disease satisfactory results were obtained in some respects, such as relief of the cough, greater freedom of respiration, less profuse perspiration, and increased appetite. But it was doubtful whether the germ itself was killed, while in the advanced stages the malady continued its normal development without being perceptibly arrested by the treatment. Without actually condemning Weigert's method, Prof. Visconti cannot at present regard it as an efficacious remedy against phthisis.—On the determination of the coefficient of dynamic and electromotor produce, by P. Guzzi. The author here describes a method of determining this coefficient, for which he claims certain advantages over that proposed by Dr. J. Hopkinson in the *Electrician* of December 3, 1886, especially in the case of engines of over 100 horse-power. His method of calculating the yield of the dynamo and electric motors is based exclusively on electric measurements made with safer and more handy instruments than Hopkinson's dynamometers. Two dynamos of about the same type and dimensions are connected together in such a way that one moves the other as motor, as in the Hopkinson apparatus. But instead of communicating to the system the *dynamic energy* required to maintain it in motion with the velocity and intensity of the normal current, Guzzi's instrument communicates the equivalent *electric energy* derived from any external source whatsoever.

Rivista Scientifico-Industriale, December 31, 1889.—Researches on the absorption of hydrogen by iron, and on the tenacity of certain metals after absorbing gases, by Prof. M. Bellati and S. Lussana. It has already been shown by Hughes (NATURE, vol. xxi., 1880, p. 602) that steel and iron immersed in diluted sulphuric acid become very brittle, and that the same phenomenon is produced when these metals are used as negative electrodes in a voltameter. Prosecuting the same line of research, the authors here describe a series of experiments tending to show that the action of electrolytic oxygen on the tenacity of platinum, and of hydrogen on that of copper and zinc, is uncertain; also, that the absorption of hydrogen produces very probably an increase of tenacity in platinum, as it certainly does in iron, but, on the contrary, a diminution in nickel. Nor can these different results be explained by the simple passage of the current, Möbius having already shown that the elasticity of metals is not perceptibly affected by this cause.—Action of arsenate of hydrogen on potassium permanganate, by D. Tivoli. Some experiments are described, from the results of which the author infers that the solution of potassium permanganate is capable of rapidly and completely absorbing arsenate of hydrogen.—S. Giuseppe Terrenzi gives a somewhat complete list of the land and fresh-water mollusks occurring in the Narni district, Umbria. This fauna presents nothing remarkable, all the species being common to other parts of Umbria, and generally to Central Italy. All are described or mentioned by the Marchese Paolucci in his "Étude de la Faune Malacologique terrestre et fluviale de l'Italie et de ses îles" (Paris, 1878).

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 30.—"On the Germination of the Seed of the Castor-oil Plant (*Ricinus communis*)." By J. R. Green, M.A., B.Sc., F.L.S., Professor of Botany to the Pharmaceutical Society of Great Britain. Communicated by Prof. M. Foster, Sec. R.S.

The work embodied in this paper deals (*a*) with the agencies which, during germination, render the reserve materials available for the use of the embryo, (*b*) with the forms in which these are absorbed by it and the mode of their absorption, and (*c*) with the parts played in the process by the endosperm and the embryo respectively.

A ferment is found to exist as a zymogen in the resting seed, which is readily developed by warmth and weak acids into an active condition. The results of its activity are the splitting up of the fat with formation of glycerine and (chiefly) ricinoleic acid. Further changes, brought about by the protoplasm of the endosperm cells, form from the latter a lower carbon acid which, unlike ricinoleic acid, is soluble in water and is crystalline. These changes do not take place in the absence of free oxygen. A quantity of sugar also is formed, which appears to have the glycerine as its antecedent.

The proteids of the seed, which consist of globulin and albumose, are split up by another ferment, with formation of peptone and asparagin.

The only products which enter the embryo are a crystalline acid, sugar, possibly some peptone, and asparagin. Consideration of the structure of the cotyledons, which are the absorbing organs, shows that the mode of absorption is always dialysis.

"Investigations into the Effects of Training Walls in an Estuary like the Mersey." By L. F. Vernon Harcourt, M.A., M.Inst.C.E. Communicated by A. G. Vernon Harcourt, F.R.S.

The present investigations were carried out with a working model of the Mersey estuary, from near Warrington to the open sea beyond the bar. The experiments were directed to the solution of two problems—namely, (1) the influence of training walls in the wide upper estuary on the channel below Liverpool, and across the bar; and (2) the effects of training walls in the lower estuary on the channel across the bar.

The experiments indicate that, whereas training walls in the upper estuary would be injurious, owing to the resulting accretion, training walls in the lower estuary would improve the depth of the outlet channel; and that such training walls, combined with dredging, offer the best prospect of forming a direct, stable, and deepened channel across the bar.

February 6.—"Memoir on the Symmetrical Functions of the Roots of Systems of Equations." By Major P. A. MacMahon, Royal Artillery. Communicated by Prof. Greenhill, F.R.S.

The object of the present memoir is the extension to systems of algebraical quantities of the new theory of symmetric functions which has been developed by the author in regard to a single system in vol. xi. and succeeding volumes of the *American Journal of Mathematics*. In the theory of the single system the conceptions and symbolism are to a large extent arithmetical, and are based upon the properties of single integral numbers and their partitions into single integral parts. In this sense the former theory may be regarded as being unipartite.

In the present generalization to the case of m systems of quantities the fundamental ideas proceed, not from a single number, but from a collection of m single numbers. In regard to number, weight, degree, part, and suffix, the collection of m numbers invariably replaces the single number of the theory of the single system. In this view the theory of the m systems is m-partite.

The quantities, to which the symmetric functions relate may be regarded as the solutions common to m non-homogeneous equations each in m variables. Schläfli, in the Vienna Transactions (*Denkschriften*) for 1852, added another linear non-homogeneous equation in m variables, and then forming the eliminant

of the $m + 1$ equations, thereby obtained an identity which is fundamental in the subject. This identity involves those symmetric functions which are here termed fundamental, and marks the starting-point of the present investigation.

In particular, three distinct laws of symmetry are established, large generalizations of those established by the author in the *American Journal of Mathematics* (vol. xi.). Of these the first two are of fundamental importance, and are examined in detail. A leading idea in these theorems, as in the whole investigation, is the "separation" of a partition; the separation bearing the same relation to the partition as the partition to the number or collection of numbers.

In conclusion, the memoir consolidates and largely generalizes the author's recent researches alluded to above.

February 13.—"On the Unit of Length of a Standard Scale by Sir George Shuckburgh, appertaining to the Royal Society." By General J. T. Walker, R.E., F.R.S.

In the determinations of the length of the seconds pendulum, which were made in London by Kater and at Greenwich by Sabine, and are described in the Philosophical Transactions for 1818, 1829, and 1831, the distance between the upper and lower edges of the pendulum was measured off on a standard scale which had been constructed by Sir George Shuckburgh. The scale had not yet been compared with any of the modern standard scales, but it had been preserved with much care with the instruments appertaining to the Royal Society.

In the autumn of 1888, M. le Commandant Defforges, an officer of the French Geodetic Survey, came to England to take a share in operations for the determination of the difference in longitude between Greenwich and Paris, and also to determine the length of a French seconds pendulum at Greenwich. He kindly undertook to comply with a suggestion which was made to him by me, to compare the portion of Shuckburgh's scale which had been employed by Kater and Sabine with one of the standard metre bars of the International Bureau of Weights and Measures in Paris. The Council of the Royal Society assented, and the scale was sent across to Paris and brought back again by special agent.

The details and results of the comparison are given in a special account by Commandant Defforges, from which it will be seen that the scale was compared with the French metrical brass scale, N, at the temperature of 48°·7 F., at which the distance between Kater and Sabine's divisions, 0 and 39·4, of the Shuckburgh scale was found equal to 1·0006245 metre. On reducing to the temperature of 62° F., which was employed by Kater and Sabine, this distance becomes 1·0007619 metre, which is equivalent to 39·400428 inches if we adopt the relation 1 metre = 39·370432 inches, which was determined by Colonel Clarke, C.B., of the Ordnance Survey, and is given in his valuable work on the comparisons of standards of length. Thus the actual length of the space 0 to 39·4 on the Shuckburgh scale may be regarded with some probability as differing by not more than about 0·0004 inch, or, say, the 100,000th part, from the quantity which the scale indicates.

Physical Society, February 7.—Annual General Meeting.—Prof. Reinold, F.R.S., President, in the chair.—The reports of the Council and of the Treasurer were read and adopted. The former stated that there had been a very satisfactory increase in the number of members during the year. The number now exceeds 360, of whom 80 are Fellows of the Royal Society. During the year the Council had proposed to change the time of meeting of the Society from Saturday afternoon to Friday evening. The change was adopted by the members by a vote of 129 to 30, and had resulted in a larger attendance at the meetings. During the year the second part of vol. i. of the translations of important foreign memoirs had been issued to the members, and it was hoped that a third part would be published early in the present session. The Council had to regret the loss by death of three well-known members—James P. Joule, Warren de la Rue, and Father Perry. A valuable collection of books had been given the Society by the Royal Astronomical Society. From the Treasurer's report, it appeared that the balance of the Society had been increased by £120 during the year. Prof. Hittorf, of Münster, was, at the recommendation of the Council, elected an honorary member of the Society. The result of the new election of officers was declared as follows:—President: Prof. W. E. Ayrton, F.R.S.; Vice-Presidents: Dr. E. Atkinson, Walter Baily, Shelford Bidwell, F.R.S., and Prof. S. P. Thompson; Secretaries: Prof. J. Perry and T. H. Blakesley; Treasurer: Prof. A. W. Rücker, F.R.S.; Demonstrator: C. V. Boys, F.R.S.; other Members of Council: W. H. Coffin, Sir John Conroy, Bart., Conrad W. Cooke, Major-General Festing, F.R.S., Prof. J. V. Jones, Prof. O. Lodge, F.R.S., Prof. W. Ramsay, F.R.S., W. N. Shaw, H. Tomlinson, F.R.S., and G. M. Whipple. Votes of thanks were then passed (1) to the Lords of the Committee of the Council on Education for the use of the room in which the Society met; (2) to the auditors, Prof. Minchin and Dr. Fison; (3) to the President and officers of the Society for their services during the year.—The meeting was then resolved into an ordinary science meeting. Messrs. E. W. Smith and C. E. Holland were elected members of the Society, and Mr. Sidney Evershed was proposed as a member.—The paper on galvanometers, by Prof. W. E. Ayrton, F.R.S., Mr. T. Mather, and Dr. W. E. Sumpner, was then resumed by Prof. Ayrton. A long table of numbers accompanying the paper, and representing the result of experiments on many galvanometers, was explained. From this it appeared that galvanometers of the D'Arsonval type were exceedingly efficient in proportion to the amount of wire used in the coils. It was for this reason that voltmeters with strong permanent magnets could be made sensitive even with an exceedingly large external resistance in series so as to diminish the power absorbed by the instrument. The space occupied by the wire was so exceedingly valuable that the extra resistance did not too much diminish the sensibility. The most sensitive galvanometers should therefore be made of the permanent magnet type. If, however, the magnets were to form part of the moving system, as in most galvanometers, the experiments showed that instruments of the Rayleigh, Gray, or Rosenthal type were the best. The coils should be numerous and small, as Mr. Boys had previously shown. As an astatic system of needles sets itself perpendicular to the earth's field, it was recommended that astatic galvanometers should be placed so that the needles pointed east and west. The controlling magnet would then not need to be turned round as it was raised or lowered. It was recommended to calibrate low-resistance ballistic galvanometers for quantity by measuring the deflection for a known current. This obviates the necessity for large condensers or high potentials. The method, although not new, is not described in text-books. In conclusion, Prof. Ayrton asked for information with regard to microscope galvanometers. C. V. Boys, F.R.S., thought that the factor of merit of galvanometers should not be given in scale divisions per micro-ampere under the condition of constant controlling moment. This gave too great an advantage to instruments of the Gray or Rosenthal type. Great sensibility could be obtained by diminishing the moment of inertia of the suspended parts, the practical limit being determined by the trouble due to the silk fibre. Spider lines, when used in place of silk fibres, gave better results. It was possible by using a good suspending arrangement to use needles ⅛″ long and a period of 20 seconds, and to gain a sensibility far greater than those indicated in the paper. Ballistic galvanometers should be made with needles as light as possible. The method proposed, of winding the central part of the coil in the opposite sense to the rest, would probably not be good, owing to the unevenness of the field produced. The conclusion come to by the author, that D'Arsonval galvanometers of great sensibility should be made with small coils placed in a very strong field, was one he had himself come to, but had finally abandoned owing to difficulties caused by diamagnetism in the copper and to excessive damping due to Foucault currents. Mr. Swinburne thought that the factor of merit of a galvanometer should be determined differently according as it was to be used for the measurement of current, or quantity, or for null methods merely. He saw no great advantage in making practical instruments proportional. The name D'Arsonval should be dropped, as the instrument denoted by it was invented by Varley years ago. He would like to know the relative sensibility of the telephone and the Lippman galvanometer. Prof. Fitzgerald stated that Lord Rayleigh had shown that the microscope method of observing angular deflections was as sensitive as the ordinary method of mirror and scale, even when only the mirror was used as a pointer, so that if a pointer were attached it would be far more sensitive. The drawback, however, was that it was impossible to distinguish with the microscope between lateral displacements of the needles and the angular motion whose measurement was required. To get over this error it was necessary to read both ends of the pointer, but this was hard to do. Prof. Ayrton replied to the different points raised in the discussion.

Entomological Society, February 5.—The Right Hon. Lord Walsingham, F.R.S., President, in the chair.—The President announced that he had nominated Mr. J. W. Dunning, Captain H. J. Elwes, and Mr. F. D. Godman, F.R.S., Vice-Presidents for the session 1890 91.—Mr. F. D. Godman exhibited a specimen of *Papilio thoas*, from Alamos, Mexico, showing an aberration in the left hind wing. Mr. R. Trimen, F.R.S., remarked that butterflies of the genus *Papilio* were seldom liable to variation.—Mr. C. G. Barrett exhibited a series of specimens of *Phycis subornatella*, Dup., from Pembroke, the east and west of Ireland, the Isle of Man, and Perthshire; and a series of *Phycis adornatella*, Tr., from Box Hill, Folkestone, Norfolk, and Reading; also a number of forms intermediate between the above, taken in the Isle of Portland by Mr. N. M. Richardson. He said that these forms proved the identity of the two supposed species, which he believed were both referable to *P. dilutella*, Hb. He also exhibited specimens of *Hesperia lineola*, and a pale variety of it taken in Cambridgeshire; specimens of *Epischnia bankesiella*, a recently-described species, taken in Portland; and a specimen of *Retinia margarotana*, H.-S., a species new to Britain, discovered amongst a number of *Retinia pinivorana*, which had been collected in Scotland.—Mr. W. H. B. Fletcher showed a series of *Gelechia fumatella*, from sandhills in Hayling Island and near Littlehampton, and, for comparison, a series of *G. distinctella*, from the same places. He also showed a few bred specimens of *G. terrella*, and a series of preserved larvæ. He stated that on the downs the larvæ live in the middle of the tufts of such grasses as *Festuca ovina* and allied species.—Mr. H. Goss read a communication from Dr. Clemow, of Cronstadt, St. Petersburg, on the subject of the coincidence of vast flights and blights of insects during the years 1510, 1757, 1763, 1782, 1783, 1836, and 1847, and the epidemic of influenza. During the year 1889 no unusual activity in the insect world had been recorded. Mr. H. T. Stainton, F.R.S., and Mr. McLachlan, F.R.S., made some remarks on the subject, the purport of which was that there was no connection between epidemics and the occurrence of swarms of insects.—Mr. G. A. J. Rothney communicated a paper entitled "Notes on Flowers avoided by Bees." It appeared, according to the author's observations, made in India, that dahlias were exceptionally attractive, but that the passion-flower was only resorted to by a few species of *Xylocopa*; and that, with one exception, he had never seen any insects feeding on the flowers of the oleander. Mr. Slater, Colonel Swinhoe, Mr. Trimen, Lord Walsingham, and Mr. McLachlan took part in the discussion which ensued.—Dr. D. Sharp read a paper entitled "On the Structure of the Terminal Segment in some male Hemiptera."—Colonel Swinhoe read a paper entitled "On the Moths of Burma," which contained descriptions of several new genera and 107 new species.—Dr. F. A. Dixey read a paper entitled "On the Phylogenetic Significance of the wing-markings in certain genera of the *Nymphalidæ*." A discussion ensued, in which Lord Walsingham, Mr. Jenner-Weir, Captain Elwes, and Mr. Trimen took part.

Zoological Society, February 4.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of January 1890.—A communication was read from Mr. W. K. Parker, F.R.S., containing an account of the morphology of the Hoatzin (*Opisthocomus cristatus*). The author treated of the early stages of the development of this Reptilian Bird, and its shoulder-girdle, sternum, and hind limbs.—A communication was read from Mr. A. D. Bartlett, containing observations on Wolves, Jackals, Dogs, and Foxes. Mr. Bartlett's remarks tended to show that all the varieties of Domestic Dogs owe their origin to Wolves and Jackals, and that the habit of barking has been acquired by, and under the influence of, domestication; also that the Dog is the most perfectly domesticated of all animals.—A communication was read from Mr. G. E. Dobson, F.R.S., containing a synopsis of the genera of the family Soricidæ. The author recognized nine genera, and divided them into two sub-families. New methods of defining the genera were introduced, each genus was briefly characterized, and remarks on certain genera, not admitted in the synopsis (although hitherto generally recognized), were appended.—Mr. F. E. Beddard read a paper containing observations upon some species of Earthworm of the genus *Perichæta*.—A communication was read from Mr. J. M. Leslie, containing notes on the habits and oviposition of the clawed Aglossal Frog (*Xenopus lævis*), as observed at Port Elizabeth, Cape Colony, where this species was said to be of ordinary occurrence.—Mr. Oldfield Thomas read an account of a collection of Mammals from Central Vera Cruz, Mexico, made by a scientific expedition organized by the authorities of the Mexican Museum, under the superintendence of Dr. F. Ferrari-Perez. The collection consisted of about 100 specimens, belonging to 21 species. Amongst these, two (a Hare and a Squirrel) were described as new, and proposed to be called *Sciurus niger melanonotus* and *Lepus veræ-crucis*.

Geological Society, February 5.—W. T. Blanford, F.R.S., President, in the chair.—The following communications were read:—The variolitic rocks of Mont-Genèvre, by Grenville A. J. Cole and J. W. Gregory.—The propylites of the Western Isles of Scotland, and their relations to the andesites and diorites of the district, by Prof. John W. Judd, F.R.S.

EDINBURGH.

Royal Society, January 27.—Rev. Prof. Flint, Vice-President, in the chair.—Prof. Calderwood read a paper on evolution and man's place in Nature. A discussion followed.

February 3.—Sir W. Thomson, President, in the chair.—Dr. William Peddie read a paper on new estimates of molecular distance. He showed that the ratio of the latent heat of vaporisation of a liquid to six times its surface-tension gives an approximation to the number of molecules per linear unit in that liquid. The liquids water, alcohol, ether, chloroform, carbon bisulphide, turpentine, petroleum, and wood spirit, have, according to this method, 50, 52, 30, 15, 19, 30, 40, and 70 millions, respectively, of particles per linear centimetre. Of course no stress is to be laid upon the relative values of these numbers; the point of interest is the complete agreement as to the order of the unknown quantity.—Prof. Tait communicated a paper by Prof. Dittmar on the gravimetric composition of water.—Mr. John Aitken read a paper on the number of dust-particles in the atmosphere of certain places in Great Britain and on the Continent, with remarks on the relation between the amount of dust and meteorological phenomena. He believes that dust condenses moisture before the air is saturated. For the same number of dust-particles per cubic centimetre, the atmospheric transparency depends upon the depression of the wet bulb, being large when the depression is large, but becoming small before the depression vanishes. Increase of temperature also reduces transparency when the number of particles remains the same, for increase of temperature means increase of vapour-pressure. As a rule, quantity of dust decreases when the wind increases. When calms occur dust accumulates. This increases the radiating power of the air, so that it cools quickly and fog forms. Thus a fog may be regarded as a suspended dew.—The dust-measuring instruments intended for use at Ben Nevis were exhibited.

PARIS.

Academy of Sciences, February 10.—M. Hermite in the chair.—Note on an unpublished memoir of Descartes', indicating the right of the author to the priority of a discovery in the theory of polyhedrons, by M. De Jonquières. Some passages are pointed out in the memoir which show that Descartes knew and applied the formula $F+S=A+2$, and furnished the elements of the demonstration, hence his name should be associated with that of Euler as an independent discoverer of the famous formula.—A physical process for the measurement of the inclination of the declination-thread of meridian-circles, by M. Hamy. With ordinary astronomical methods this value can be determined to within half a degree, but using the process described, it is possible to obtain it within a few seconds. The complete description will be given in the coming number (January) of the *Bulletin Astronomique*.—Upon the exponential function, by M. Stieltjes. A demonstration is given of a relation of the form

$$N+e^aN_1+e^bN_2 \ldots \ldots +e^hN_n=0 \quad \ldots \ldots (1)$$

$a, b, \ldots, h$ being whole numbers, $N, N_1, N_2, \ldots N_n$ coefficients. Starting with the polynomial function

$$F(z)=z^\mu(z-a)^{\mu+k_1}(z-b)^{\mu+k_2} \ldots \ldots (z-h)^{\mu+k_n}$$

the author deduces that assuming (1) to hold

$$\int_0^h \phi(z)e^{-z}F(z)dz=0,$$

and then proves this function not to hold if μ be an even number.—Note on a method of transformation in kinematic geometry,

by M. A. Mannheim. In a preceding communication the author has shown how to transform the properties relating to the displacement of a straight line, of which the points describe trajectory surfaces; he now extends his method to the case where the points of the movable line describe trajectory lines only, and taking as examples several theorems relating to the former case, derives therefrom corresponding theorems in the latter.—On a generalization of Euler's theorem relating to polyhedrons, by M. R. Perrin. Attention is drawn to some relations bearing upon Euler's formula, published by the author in 1882 (*Bulletin de la Société Mathématique de France*, t. x.).—On bodies which give a tension of dissociation equal to the tension of the vapour of their saturated solutions, by M. H. Lescœur. Experiments are referred to which are antagonistic to the theory of M. Bakhuis-Roozeboom. According to experiment, the curves representing the tensions referred to as functions of the temperature are tangential, and do not intersect at an acute angle as required by the theory.—Action of fluorine upon different varieties of carbon, by M. Henri Moissan.—A general method for the preparation of fluorides of carbon, by M. C. Chabrié.—On the blue flame of common salt and the spectroscopic reaction of copper chloride, by M. G. Salet. The author finds that the bands seen in the spectrum of salt burning in a common fire, and of which the strongest are situated in the indigo and blue-green, are due to copper chloride, and coincide with bands given by Lecoq de Boisbaudran in his "Spectres Lumineux."—On the electrical resistance of iron and its alloys at high temperatures, by M. H. Le Chatelier. The electrical resistances for a considerable range of temperature of a number of iron alloys have been examined. When the results are graphically shown, the curve for ferro-manganese (13 per cent. Mn) is found to be regular, just as is the case with platinum or platinum-rhodium alloy, while the curves for mild and hard steels show distinctly two singular points at 820° and 710°, and a silicon steel (Si = 3 per cent.) shows the former only. Ferro-nickel (25 per cent. Ni) behaves very peculiarly, as below 550° two modifications having quite distinct properties exist, and nickel itself shows a sudden change of curvature at 340°.—Thermochemical researches upon silk, by M. Léo Vignon. Investigations have been made to determine the heat disengaged when various reagents are absorbed by raw and prepared silk. A discussion of the results seems to indicate that the method may be employed to elucidate the theory of dyeing.—Estimation of potassium and humus in soil, by M. J. Raulin. A method of estimating potassium by weighing it on a tared filter as phosphomolybdate is described, together with the application of the modified permanganate process of J. H. Schmidt to the determination of humus.—On a colouring-matter from Diaptomus, analogous to the carotin of vegetables, by M. Raphael Blanchard. The colouring-matter, isolated from these animal organisms, is shown to differ considerably in spectroscopic properties and in its solubility in alcohol from the lipochromes, and it does not prove to be identical with any of the red pigments from the Cœlenterata, Echinodermata, Bryozoa, or Mollusca; while on the contrary it is found to show many analogies to carotins ($C_{26}H_{38}$), which are so marked as to lead to the conclusion that it is itself a carotin and so possesses great interest as a colouring substance common to both the animal and vegetable kingdoms, and as an instance of the production of a hydrocarbon by animal agency.—On the intercellular substance, by M. Louis Mangin. It is shown that among Phanerogams and Cryptogams (with the exception of Fungi and many Algæ) the tissues of the softer parts are composed of cells cemented together by an intercellular substance composed of insoluble pectates.—On the localization of colouring-matters in the seminal integuments, by M. Louis Claudel.—Formation of quartz at the spring of Maubourot at Cauterets, by M. Beaugey.—On the existence of leucite rocks in Asia Minor, and on some hypersthene rocks from the Caucasus, by M. A. Lacroix. It is found that the leucitic rocks from near Trebizonde fall under two main types, leucitite and leucotiphrite.—Upon the composition of some pseudo-dolomitic chalks from the north of France, by M. L. Cayeux.

Berlin.

Meteorological Society, January 7.—Dr. Vettin, President, in the chair.—Dr. Wagner spoke on the behaviour of water in the soil. The relationships between surface water and springs and deposits, possessing as they do a distinct meteorological interest, have as yet been but slightly investigated, probably because the behaviour of water in soil occupies the border-land between the subjects of meteorology, geology, agriculture, and hygiene. A review of scientific investigations which have so far been made on the subject of surface water and the formation of springs, shows that the problems of most importance are still awaiting their solution. In the speaker's opinion the task to be undertaken in the interests of meteorology is the establishing of as many lysimeters as possible, so that by keeping a continuous record of their indications a continued set of observations on surface water would be provided. He further considered it to be essential that the relationship of water to the soil should be investigated at depths far greater than has as yet been the case. A lengthy discussion followed the above communication, which turned chiefly upon a consideration of the forces, as yet but little known, which determine the collecting of water on internal impervious layers of the earth.—Prof. Spörer gave a short statistical statement on sun-spots during 1889. The chief point of interest was that the spots appeared during the first half of the year in the lower latitudes and in the second half in the higher. Taking the year as a whole, there were considerably more spots in the southern than in the northern hemisphere; this has been the case in each year since 1883.—The Secretary then handed in his annual report, and the Society proceeded to elect its officers for the year 1890. Prof. Schwalbe was elected President.

Physical Society, January 27.—Prof. Kundt, President, in the chair.—The President opened the meeting by a short address in memory of civil engineer G. A. Hirn, who died recently at Logelbach in Alsace.—Dr. Lehmann spoke on the testing of tuning-forks. After the International Congress met for the establishing of a uniform standard of tone, and selected for this purpose a vibration frequency of 435, it devolved upon Government to construct a standard fork, and to devise some ready method for testing ordinary forks to an accuracy within half a vibration per second, and standard forks within 0·1 of a vibration. The speaker discussed the various methods in use for comparing two forks and for counting the number of vibrations per second which they yield. For the first purpose the vibrations of the respective forks are employed, these being observed either acoustically or optically; a further means of effecting the comparison is by the stroboscopic method or by the acoustic wheel. The vibration frequency of a fork is determined either graphically or by means of a tuning-fork clock, or by means of the undulations obtained by oscillating or rotating acoustical instruments. An important factor in all these methods is the temperature of the fork. To determine this a special thermostat is employed, by means of which the fork can be set in vibration in an air-bath whose temperature is constant and accurately known. The standard fork for reference is one of König's, whose vibration-frequency has been accurately determined by several methods. The comparison of any new fork with the standard is made by means of the acoustic wheel, and by a simultaneous graphic recording of the movements of the fork which is vibrating inside the thermostat, and of the magnetic interrupter; the latter consists of a tuning-fork vibrating to the octave below the note yielded by the standard fork.—Dr. Eschenhagen exhibited curves of the three elements of terrestrial magnetism recorded by the new instruments in the Observatory of Potsdam, and gave a short description of the arrangement of the apparatus. The curves were taken on white photographic paper, and were of such dimensions that the greatest variations which have as yet been observed were completely recorded.—Prof. Kundt exhibited some quartz-fibres which he had received from Prof. Weinhold. He made, in addition, some remarks on the preparation of these fibres by Boys's method, and gave some data as to the dimensions of an apparatus which Prof. Weinhold had constructed for the measurement of gravitation constants, and had employed in several determinations.

Amsterdam.

Royal Academy of Sciences, Dec. 28, 1889.—Prof. van de Sande Bakhuyzen in the chair.—M. Hugo de Vries related the results of the scientific researches made by the Committee of Advice, appointed in July 1887 at Rotterdam, to report on the appearance of Crenothrix in the drinking-water of the Rotterdam water-supply. He gave an account of the organisms met with in the mains and basins before and after the filtration of the water, and of the degree of the pollution caused by these creatures in the colder and warmer months of the year. He spoke also of the influence of darkness on the water-organisms, which, under ordinary circumstances, live in the sunlight; of the

proposals made by the Committee to mitigate or remove the evil; and of the improvements effected, or about to be effected, in accordance with those suggestions.—M. Kapteijn treated of chronographical observations for the purpose of determining parallaxes of fixed stars. After having explained the precautions taken to prevent systematic error, he gave the results and subjected them to several tests showing their absolute trustworthiness within the limits defined by the probable errors.

Jan. 25.—Prof. van de Sande Bakhuyzen in the chair.—M. Hoogewerff, giving an account of joint work by himself and M. van Dorp, spoke of the action of potassium hypobromite on succinphenylamide, and on the amide of cinchonic acid.—M. van Bammelen communicated certain results of a research relating to the composition of volcanic and other soils, on which, in Deli and Java, tobacco is cultivated. The extraordinary fitness of the soil of the cleared forest grounds in Deli for the production of exquisite tobacco is to be attributed, he thinks, to the peculiar composition of the amorphous silicate occurring therein, to the looseness of the forest soil, and to the auspicious climate with regard to the rainfall. He concluded by insisting on the urgent need for the establishment of a scientific experimental station at Deli. Such an establishment would be favourable to the culture of tobacco, and would enlarge our knowledge of the soil, of the vegetable world, and of geological formations.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, FEBRUARY 20.

ROYAL SOCIETY, at 4.30.—A Comparative Study of Natural and Artificial Digestions (Preliminary Account): Dr. A. Sheridan Lea.—On a Fermentation causing the Separation of Cystin: Sheridan Delépine.—Some Stages in the Development of the Brain of Clupea harengus: Ernest W. L. Holt.

LINNEAN SOCIETY, at 8.—On the Fruit and Seed of Juglandia; on the Shape of the Oak-leaf; and on the Leaves of Viburnum; Sir John Lubbock, Bart., P.C., M.P., F.R.S.

CHEMICAL SOCIETY, at 8.—The Behaviour of the most Stable Oxides at High Temperatures: G. H. Bailey and W. B. Hopkins.—The Influence of Different Oxides on the Decomposition of Potassium Chlorate: G. J. Fowler and J. Grant.

THURSDAY, FEBRUARY 27, 1890.

THE NEW CODES, ENGLISH AND SCOTCH.

THE country is once more within a month of a new Education Code. Once more the Lord President and the Vice-President of the Council are being besieged by representatives of all interests and opinions, anxious to impress them with the exclusive importance of their particular views. Last year, it will be remembered, the Code—great advance as it was on its predecessors—fell a victim to the fears of one party and the lukewarmness of the other. The extreme School Board partisans gave but scant support to any scheme which did not practically embody the recommendations of the minority of the late Royal Commission, while the champions of voluntary schools shrank from any changes which, by raising the standard of efficiency, seemed likely to accentuate the difference between the Board school, which has the ratepayers' pocket to draw on, and the voluntary school, which depends on a fast-shrinking fund of private subscriptions. And so the Code was sacrificed, and the friends of education were condemned to wait another year.

This is what is constantly happening, and what will continue to happen, so long as there are ten experts forthcoming on all matters relating to educational machinery for one who knows and cares about education itself. Whether elementary schools should be free; whether they should be under representative control; whether they should all receive rate-aid—these and the like disputes are always sure to gain the ear of the public, while the problem of making the education provided worth disputing about is passed by almost unnoticed.

How few among our so-called "educationists" (a newly-introduced word with an ominous ring about it) ever sit down deliberately to face the central problem of elementary education—the only problem of fundamental importance: Given a child between the ages of 5 and 13, with the limitations imposed by its age, by its home surroundings, by the pressing necessity that it should begin to earn a living as soon as possible, and by the fact (most neglected of all by theorists) that there are only a certain number of school hours in the day—what is the best kind of training through which it shall pass? How can those few precious years be best utilized?

Theories, indeed, there are, enough and to spare, till we could wish sometimes that all those in high places who talk of education were made to go through an apprenticeship as school managers, in order to gain some practical acquaintance with the limits imposed on the range of instruction by the nature of the child-material with which they have to deal. For no designer trained to make "designs-in-the-abstract"—who produces patterns for carpets which cannot be woven, for wall-papers which cannot be printed, for copper that cannot be beaten, and for wood that cannot be carved—could be more out of touch with the material in which his designs have to be executed than the educational "reformer-in-the-abstract," who sketches fabulous plans for Universal National Systems of Education which have only one defect—that they are impossible to carry out.

And now, having relieved our feelings, we may turn to the question of immediate importance—namely, the prospects of educational advance under the new Code which is so eagerly expected.

It is rumoured that the authorities at the Education Department are earnestly engaged in the attempt to make the Code a real advance on former efforts. They have many difficulties. If they can successfully run the gauntlet of the Treasury, they have to reckon with the factious criticism of political partisans. We hope, however, that we may assume that the draft Code as it issues from the Department will embody at least all the purely *educational* reforms which appeared in its unlucky predecessor. The clause requiring English as a class subject will go, the curriculum and regulations for evening schools will be made more elastic, an attempt will be made to spread the teaching of drawing, and further facilities will be afforded for science instruction at central schools and classes. It will be the task of outside critics to see that these proposals, already made in last year's Code, are not whittled down, and that they are supplemented by other changes on which al educational reformers are practically agreed. What these changes are may be gathered from the discussion on elementary education, especially in its relation to scientific and technical instruction, which followed Dr. Gladstone's paper at the Society of Arts last November. The programme has been since embodied in a more definite and concrete form in the suggestions which have just been submitted to the Education Department by the Committee of the National Association for the Promotion of Technical and Secondary Education. Among other suggestions they propose that drawing should be made compulsory in boys' schools, of course being allowed a due interval before the regulation comes into operation, during which schools may adapt their staff for the purpose. Elementary drawing should be introduced into infant schools for boys to correspond to needlework for girls, as proposed in last year's Code. The absurd minute of the Science and Art Department—forced on them, it is only fair to say, by the Treasury—confining grants on drawing in girls' schools to departments where cookery is taught, ought of course to be repealed; not so much in the interests of the girls, as of the boys in mixed schools, for whom under the existing regulations provision for drawing cannot well be made. Drawing is not only the basis of all technical instruction, but is a subject of very high educational value, and on both grounds its spread is much to be desired. A further change which is to be hoped for is the extension of the Kindergarten methods from the infant school into the lower standards, and their continuation by means of graduated object-lessons so as to lead up to more distinctive scientific and manual instruction for the more advanced scholars of the school. Manual instruction of some kind ought to be introduced throughout boys' schools to balance needlework instruction for girls.

By manual instruction we do not merely mean instruction in woodwork (called, rather unhappily, the "use of tools" in the recent Act), which is evidently only suitable for the higher standards, say the sixth and seventh. We doubt if it can be profitably given to children below the age of 11, and even in the case of these it can of course only take the form of the "hand and eye" training—not of specific

S

instruction in carpentry. For younger children, however, much might be done in the way of modelling (or, as it has been called, "applied drawing"), designed to carry on the training of the fingers which are often made so nimble by the paper-cutting and the Kindergarten exercises of the infant school, only at present to lose their pliancy and dexterity by want of practice as soon as the child emerges from the fairy-land of the Kindergarten into the dull, prosaic atmosphere of Standard I.

To introduce this change it will doubtless be necessary to abolish individual examination in the lower standards at least, and assimilate them in this respect to the infant school. Another change will also be necessary, in the mode of interpreting the Education Acts which has hitherto been customary at Whitehall. Up to the present time there has been a tendency in the Government Departments to decline to recognize manual training as a form of instruction contemplated by the Acts, and in the well-known case of the Beethoven Street Board School, the London School Board were surcharged by the auditor with the cost of tools. The School Board failed to carry the question to the law courts, and so for a time the matter rested. Since then, however, the question has entered on a new phase. The Liverpool School Board, wishing to provide manual instruction in its schools, has obtained the opinion of Sir Horace Davey, Q.C., to the effect that such provision clearly comes within the power of School Boards. The Board has consequently taken steps to make the necessary provision, has appointed an instructor, and now only waits to be surcharged in order to carry the whole question to the Queen's Bench. Other School Boards are following suit, so that we must very shortly see the matter settled in one way or another. The legal question is interesting, not only in its bearing on manual training, but on the general powers of School Boards to give *any* extra instruction they please, provided they comply with all the regulations and requirements of the Education Department for the time being. If Sir Horace Davey's opinion is sustained, it carries with it the right of School Boards to provide any form of technical or manual instruction that can be given consistently with the regulations of Whitehall. Up to the present year, as we stated above, the Education Department was not altogether favourable to the views of Sir Horace Davey. But it is rumoured that of late the views of the authorities on the subject have undergone a change, and that it is probable that manual instruction may not only be recognized as legal, but actually incorporated as a grant-earning subject in the forthcoming Code. The rumour, which we sincerely hope is true, is confirmed by the fact that in the Scotch Code just issued a clause is inserted for the first time inviting school managers to submit as a class subject (earning a grant of 2*s*. or 1*s*. a head) "a course of manual instruction on a graduated system." The Scotch Education Department, therefore, has conceded the whole principle, and though of course Scotland has a separate Act, the admission is full of significance. It would be a trifle too absurd for the English Education Department to refuse to "recognize as educational" a subject which the Scotch Office thinks important enough to be encouraged by a grant.

In other respects the new Code just issued from Mr. Craik's office is a valuable index, if not of what we shall get, yet of what we may justly press for, in the coming English Code. It is, indeed, an enormous advance. Scotch members of Parliament sometimes complain that Scotch business attracts no attention at Westminster. The evil, however, has at least some compensating advantages. Unchallenged—almost unnoticed—the officials at the Scotch Education Office can quietly introduce by a stroke of the pen the reforms in the Code for which we in England have to wait year after year. It may serve a useful purpose if we recount a few of the reforms which Mr. Craik has been able to carry out this year in Scotch education. Of the abolition of fees we say nothing, for that was the result of legislation last session.

In the first place, individual examination in the elementary subjects, which had already been abolished in the first three standards, is now replaced by collective examination throughout the school. This change gives much greater elasticity and liberty of classification to the teacher, and to a great extent modifies the pressure of the system of payment by results.

In the next place, the system of class subjects is entirely revised. Several alternative courses in elementary science are suggested, including courses of "nature knowledge" in "animals," "vegetables," and "matter," for each of which simple and suitable suggestive syllabuses are laid down. Any other progressive scheme of teaching may be submitted to the inspector for approval. "In elementary science this scheme may be so framed as to lead up to the teaching of scientific specific subjects. It may include the subjects of navigation or the elementary principles of agriculture; and a course of manual instruction on a graduated system may also be submitted."

At the same time the regulation requiring either English or elementary science to be taken as one of the class subjects is rescinded. It is to be noticed that in Scotland an attempt was made in the previous Code to encourage science teaching by making it alternative to English as a compulsory class subject. It is somewhat disappointing to be told, as we are in the last Scotch Report, that the change has as yet produced but little increase in science teaching. This fact seems to support the suggestion of the Technical Association that science instruction (which gives more trouble and requires more appliances) should be encouraged by a slightly higher scale of grant than that allotted to other class subjects. But it also tends to suggest the possibility that part of the price which Scotland has to pay for the ease with which it can get educational changes carried out is a certain popular indifference to those changes which may go far to make them nugatory. Thus it is quite possible that the Departmental invitation to submit courses of manual instruction may produce far less effect on schools in Scotland than would be produced in England by a favourable decision of the law courts on a hotly disputed case such as that which may come before them in connection with the Liverpool School Board. The steam which has to be got up on this side of the Tweed in order to get a reform permitted will often supply the motive force which will get that reform carried out. The different fate which has attended the Scotch and the English Technical Instruction Acts hitherto is a case in point. The Scotch Act, passed with ease through

an apathetic House, has fallen flat, while the English Act, badly drawn as it is, is arousing a great and increasing amount of interest in the country, and within the first six months is already in full swing in several districts.

But this is a digression. The recasting and improvement of the system of class subjects in Scotland is interesting not only in itself but as indicating a probable change of a similar kind in the English Code. Under these circumstances we must not fail to note the parallel change carried out in the schedule of "specific subjects." Almost the whole of the schedule which relates to science subjects—chemistry, mechanics, electricity, light and heat, physiology, botany, and physical geography—is entirely cancelled, and for the detailed syllabuses of these subjects is substituted a simple invitation to school managers to submit graduated courses in subjects not mentioned in the schedule. At first sight this seems a loss—as though the Department were moving in the direction of paying less instead of more attention to science. The alteration, however, must be read in conjunction with the reforms in class schedules and the observations on class and specific subjects in the last Report of the Scotch Education Department. Commenting on the fact that "the general development of class subjects tends to restrict the specific subjects," the Report proceeds: "this is a result not altogether to be regretted, as the influence of the class subjects is general, while that of the specific subjects is restricted to a few selected scholars."

Again, in the instructions to inspectors just issued, Mr. Craik explains one of the objects of the Department to be "to spread the beneficial results of any such higher teaching as may be given, to the whole school, instead of confining it to a few selected scholars."

It is clear, therefore, that the changes in the fourth and fifth schedules (which are probably the precursor of similar changes in the English Code) are dictated by a desire to extend class instruction in science, even if at the expense of specific subjects; in other words, to transfer natural science from its former position, as a smattering of a few special branches of physics imparted to a few pupils, to its proper place as a course of general stimulating instruction in the elements of "nature knowledge," given as an integral part of the school course to the school as a whole. More specialized science teaching can still be provided if desired in the form of specific instruction framed to suit local wants by the various school managers, or it may be given, as is already the case in many elementary schools, by means of science classes in connection with the Science and Art Department.

We cannot doubt that the Scotch Department is right in its policy, but the probable extension of class teaching under the new and more elastic *régime* suggests a doubt whether the proper way of introducing manual instruction is by means of including it among the class subjects, so long at least as the possible number of class subjects is restricted. Drawing—the only form of manual training previously recognized for boys—has already been put outside the range of class subjects. Needlework—the only other manual subject in the Code—may be taught either as a class subject or as part of the ordinary curriculum of the school. Is there not a chance that in including manual instruction among the class subjects an unnatural rivalry may be set up between this subject and elementary science, which may restrict the spread of both? All this, however, is a matter for the future. Meanwhile we have only to congratulate the Scotch on the improvement of the conditions under which in the future their schools will be carried on, and to express the hope that England will not lag behind.

One word in conclusion. It may be wondered why in this article, dealing with scientific and technical instruction in elementary schools, so little reference is made to the Technical Instruction Act of last session, either in respect of the powers which it confers on elementary school managers, or of those which, much to the regret of many politicians, it appears to withhold.

The real fact is that we have our doubts as to the need of any general Technical Instruction Act for elementary schools, and have a suspicion that their exclusion from the late Act was in reality a blessing in disguise. Of course, if the opinion of Sir Horace Davey (and now we are glad to be able to add, of the Scotch Education Department) should be upset in the law courts, it may be necessary to rectify the anomaly by a short Act of a single clause recognizing the legality of manual instruction. But, with this possible exception, no new powers are required by School Boards, and no new rate need be imposed. Mr. Mundella, in complaining of the exclusion of elementary schools from the late Act, compared the scheme to an educational ladder with the lower rungs left out. Let him be reassured—no rung is wanting so far as legislation is concerned. As at present advised, we feel clear that the managers of a public elementary school, so long as they comply with the requirements of the Department, may teach what extra subjects they please. The rating power possessed by a School Board is limited only by the wishes of the ratepayers. What really retards the introduction of technical and manual instruction is the want of imperial grants (which may and ought to be given through changes in the Code), the want of time, the pressure of other subjects, the ignorance of the public, and the parsimony of the ratepayers. But none of these obstacles can be removed by legislation. What legislation could and probably would do, would be to restrict the present powers of School Boards by defining them; and, perhaps, even to confine the rate for technical instruction within the limit of a penny in the pound. But this can hardly be what Mr. Mundella wants.

A DICTIONARY OF APPLIED CHEMISTRY.

A Dictionary of Applied Chemistry. By T. E. Thorpe, B.Sc. (Vict.), Ph.D., F.R.S., &c. Assisted by Eminent Contributors. In Three Volumes. Vol. I. (London: Longmans and Co., 1890.)

THE first volume of the "Dictionary of Applied Chemistry," edited by Prof. Thorpe, is a welcome addition to our scientific books of reference, and forms an admirable companion to the "Dictionary of Theoretical Chemistry," the second volume of which was reviewed some weeks ago.

In the preface Prof. Thorpe points out that, as this

work has special reference to the applications of chemistry to the arts and manufactures, it deals but sparingly with the purely scientific aspects of the science, unless these have some direct and immediate bearing on the business of the technologist. How direct and how immediate such a bearing is at the present day, and how difficult, not to say impossible, it is to separate theory from practice, may be judged of by turning over the pages of this most useful volume.

Take, for example, the article on the azines, written by the most competent authority on that subject, Dr. Otto Witt, of Berlin. The untrained technologist will be completely at sea with the honeycomb of benzene rings with which he clearly explains the constitution of such well-known compounds as the safranenes, the splendid yellow dyes so ably investigated by Dr. Witt himself, whereas the manufacturer who has the theory of the subject at command is complete master of the situation. Or, again, let us turn to the next article, on the azo-colouring matters, communicated by another equally trustworthy authority, Prof. Meldola, covering 28 thickly-printed pages, in which the same necessary connection is seen. And no other example, perhaps, indicates more forcibly the enormous advance which applied chemistry has made in the last ten years, and its entire dependence upon abstract research. In proof of this, it needs only to be pointed out that the article concludes with a list of no less than 95 distinct patents on this one group of colouring matters, from March 12, 1878, to June 30, 1888, all of which are the result of original, chiefly German, research.

An examination of other important articles written by specially-qualified contributors indicates that each subject is brought up to the level of the present state of our knowledge. Let us look for a moment at the article on ammonia, contributed by Prof. Lunge, of Zurich. Here we find detailed reference to the newest forms of apparatus for the manufacture of ammonium salts, illustrated by excellent woodcuts of the Feldmann-still. Again, turning to the article on chlorine, we have to note the same completeness and technical grasp of the questions discussed. Thus, on p. 526, we find the method patented so long ago as 1866 by Mr. Brock, of Widnes, and now for the first time coming into general use, which has for its object the treatment of the exit gases from the bleaching-powder chambers by means of a dry lime-sprinkler, this not only removing a serious nuisance in the manufacture, but also recovering chlorine otherwise wasted.

Prof. Hummel, of Leeds, contributes an excellent article on bleaching; and here again we see that the newest processes are fully described, *e.g.* on p. 323 the Mather-Thompson bleaching process is fully noticed, and the electrical bleaching process of Hermite likewise referred to. As regards this latter, the conclusion arrived at is that now generally admitted by practical authorities, viz. that electrolytic bleaching cannot reasonably be expected to replace bleaching-powder at a price of £7 per ton.

One of the most valuable articles in the book is written by Mr. John Heron on brewing, in which he not only describes the most modern forms of brewing plant and processes, but gives a clear statement of the important researches of Pasteur and Hansen on the alcoholic ferments. As we all know, it was Pasteur who first directed attention to those other forms of Saccharomyces known as "wild" yeasts in fermenting yeasts and beer; but it is not so commonly understood that it was Hansen who taught us how to introduce into the liquid a seed yeast really free from "wild" forms. Since 1883 carefully selected types of yeast from pure cultures, according to Hansen's researches, have been introduced into Denmark, Norway, and Bavaria, with the most satisfactory results, whilst in England nothing of the kind has yet been done, although, at Burton several experiments have been made in this direction. Sufficient has already been done to show that several varieties of *Saccharomyces cerevisiæ* can be separated, which, however, do not differ morphologically, but may be distinguished from each other, inasmuch as they give entirely different results, both as to flavour brightness, attenuation of the beer, and to the mode of separation of the yeast. The proportion of these different varieties in various breweries seems to remain constant, and to give the peculiar flavour and appearance which the various fermented liquors possess.

Another article is that by Prof. Noel Hartley on cements, a subject which though of great importance is not usually considered of great chemical interest, but it has been made so by the writer. He points out the fact, certainly not known to the majority of chemists, that we owe to Lavoisier the first explanation of the phenomena of the baking and hardening of plaster of Paris. At so early an age as 21, he published a short note in the *Comptes rendus* of February 17, 1765, in which he showed that water is removed from the gypsum in two stages, that the first three-quarters of the combined water must be removed in order that the plaster shall afterwards set, but that if the whole of the combined water be removed, the gypsum becomes overburnt and loses its value as plaster.

It is probable that this volume will have even a larger sale than that of the corresponding "Dictionary of Pure Chemistry," and, as with that important work, so with this, the public may well be congratulated on possessing such a valuable book of reference so creditable to all concerned in its production.

H. E. ROSCOE.

OATES'S ORNITHOLOGY OF INDIA.

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by W. T. Blanford. *Birds.* Vol. I. By Eugene W. Oates. Pp. i.—xx., 1—556. (London: Taylor and Francis, 1889.)

The Nests and Eggs of Indian Birds. By Allan O. Hume, C.B. Second Edition. Edited by E. W. Oates. Vol. I. Pp. i.—xii., 1—397. (London: R. H. Porter, 1889.)

THE two volumes on the birds of India, which Mr. Oates has recently published, will supply a much needed want. The period of twenty-six years which has elapsed since the publication of Jerdon's "Birds of India" has been prolific in ornithological work, to such an extent that a new adjustment of the scattered details which had accumulated since that time had become an

absolute necessity. Mr. Oates has already won his spurs in the field of Indian ornithology; for his "Hand-book of the Birds of Burma," published in 1883, has always been looked upon as a standard work; and by coming to England, at great personal sacrifice, to write the bird volumes of the "Fauna of British India," he has deserved the gratitude of all zoologists. Those of us who are acquainted with the "Hand-book" before mentioned, will not be surprised to find that in the present volumes Mr. Oates has done his work in a thoroughly conscientious manner. Without commencing, as Jerdon did, with a general outline of ornithology, for which space was not available, Mr. Oates has contrived to give a condensed introduction, which will give the student some small idea of classification of passerine birds, with which this volume deals. We could have wished that the author had followed a more natural arrangement of passerine families, as his scheme of arrangement results in some very incongruous affinities, but these will doubtless be further explained when the author gives a detailed arrangement of the orders and families of birds in his third volume. As the furlough which has been granted to Mr. Oates is quite insufficient for him to finish the work in anything like a reasonable period, we are glad to learn that a representation has been made to the Government of India, by some of our leading men of science, for a further extension of leave, to enable the author to finish the work, which he has begun so creditably. It would be a thousand pities to see the completion of this book intrusted to less capable hands, of which there seems to be some fear expressed in Mr. Blanford's preface.

Since Mr. Seebohm, in the fifth volume of the "Catalogue of Birds in the British Museum," laid stress on the importance of the plumage of the young as distinguishing characters between the Thrushes and the Warblers, this character has been thoughtfully considered by many ornithologists; but Mr. Oates has been the first to apply it in any large measure to the bulk of the passerine birds, and it enables him to divide them into five sections, characterized by the plumage in the nestling. This arrangement brings about some rather startling results, for the Titmice (*Paridæ*) become merged in the family *Corvidæ*, and the Dongos (*Dicruridæ*) range in close proximity to the Nuthaches (*Sittidæ*) and the Creepers (*Certhiidæ*). This character of the plumage of the nestlings, like all single characters, carries the author too far, and it is becoming more and more plain every day that the natural classification of birds in the future will be founded on a combination of characters, not on any single one alone. Mr. Oates himself, in his arrangement of the *Crateropodidæ*, shows how this can be done.

It is impossible to praise too highly the method in which the present book has been worked out, though it is to be regretted that four volumes were not allowed for the birds, instead of three, for the constriction of the work has compelled the author to treat of 563 species in 544 pages, which is an allowance of less than a page to each species, including the space necessary for family characters and "keys" to genera and species. We notice that the author has been driven to create a good many new genera, but we are not disposed to quarrel with him on this account, though we notice that, like ourselves, in writing the "Catalogue of Birds," he has found it hard to be consistent, and he certainly varies somewhat in his estimate of characters in different families. Thus he divides the Bulbuls into a number of slenderly defined genera, yet he places the Rook and the Jackdaw in the same genus, *Corvus*, as the Raven. What was sauce for a Bulbul ought to have been sauce for a Rook! It is very interesting to notice the immense strides which our knowledge of Indian ornithology has made in the last twenty years. This is mostly due to the energy of Mr. Allan Hume, whose marvellous collection of Oriental birds was given by him to the British Museum in 1885. Since that date the registration and arrangement of the Hume Collection, has occupied the bulk of our own time and that of our colleagues in the Bird Room, so that the whole of the Indian Passeres have been placed conveniently at Mr. Oates's disposal for the present work. It may, indeed, be said that Mr. Hume sowed, the officers of the British Museum watered, and Mr. Oates came over from India in time to gather the increase. It must be a great pleasure to Mr. Hume, and to Major Wardlaw Ramsay, who gave the Tweeddale Collection and Library to the Museum two years ago, to see that already their magnificent donations have been turned to such good account.

The number of new species described by Mr. Oates is, as might be expected, small; but ornithology has now reached a stage when the description of new species will be surpassed in interest by the study of greater facts, of which the geographical distribution of birds is likely to prove the most absorbing. For this purpose the splendid Collection of skins amassed by Mr. Hume will be invaluable, for in most instances the specimens in the Hume collection trace out definitely the range of each species, and Mr. Oates has shown great talent in condensing into his limited space the large amount of material which was at his command. It is, in fact, impossible to speak too highly of the way in which he has performed his task.

The volume before us is profusely illustrated with woodcuts, which will undoubtedly be of great service to the student in enabling him to identify the species of birds which are to be met with in India. These woodcuts are, almost without exception, well executed, and are the best specimens of ornithological work which we have seen from the pencil of Mr. Peter Smit. We are not quite able to grasp the plan on which the names of Indian localities have been altered in the present book to bring them into a recognized system of correct orthography, but we suppose that there is some sound reason for the changes. If, however, our old friend "Mooleyit" is to become "Muleyit," and "Malewoon" to become "Malawun," why does not "Masuri" take the place of "Mussoorie"? Surely it is pedantic to alter the specific name of "nipalensis" to "nepalensis," because it suits modern notions to speak of "Nepal" instead of "Nipal." As this mode of orthography does not appear in any of Mr. Oates's previous writings, we suppose that the editor is responsible for the changes in the spelling of the names of places. We would gladly adopt a complete method of spelling the names of Indian localities, but that adopted in the present work seems neither one thing or the other.

It was a happy idea of Mr. Oates's to issue the new edition of Mr. Hume's "Nests and Eggs of Indian

Birds" in volumes of simultaneous issue with his volumes of birds. This egg-book of Mr. Hume's is one of the best oological works ever published, and has long been out of print. A good deal of the additional matter which Mr. Hume had accumulated for a second edition, was stolen by a dishonest servant, and sold for waste paper in the Simla Bazaar, but enough has remained to enable Mr. Oates to put before us a very interesting record of the breeding habits of Indian birds; and if any tribute be wanted to Mr. Hume's energy and ability, the reader has but to refer to the present work, to study the oological records of the best circle of field-ornithologists which ever rallied round the central figure of any zoologist. The portraits of naturalists who have contributed to the development of our knowledge of Indian birds lend an additional interest to Mr. Oates's volume on the "Nests and Eggs of Indian Birds."

R. BOWDLER SHARPE.

EPHEDRA.

Die Arten der Gattung Ephedra. Von Dr. Otto Stapf. Pp. 112, 1 Map and 5 Plates. (Vienna: R. Tempsky, 1889.)

EPHEDRA is one of the three genera of the small Gymnospermous order Gnetaceæ, the two others being Gnetum and Welwitschia, that most curious of all gymnospermous plants. Ephedra is a type of remarkable habit, specially modified, though in a different way from Welwitschia, to inhabit the dry and sandy regions of the world. It has shrubby stems, with copious slender, whip-like, straight or turning branches, foliar organs and flower-wrapper reduced to a minimum, unisexual mostly dioicous flowers in small catkins with dry imbricated scales, the female catkins containing one or two flowers only, and the males several, with from two to eight stamens with the filaments usually joined in a column. The species are numerous and difficult of determination, partly because the leaves are nearly suppressed, partly because the stems of all the species are very similar, and that it is needful to have both staminate and pistillate flowers to study before any given plant can be determined confidently.

The map shows clearly at a glance the geographical range of the genus. It surrounds the basin of the Mediterranean, climbs the lower levels of the Central European Alps, attains its highest development in Central Asia, reaching southward to the north of India and all through Arabia, northward to Lake Baikal and the Ural Mountains, and eastward to the western provinces of China; and reappears in the New World—in North America in California and Mexico, and in South America in the Andes and over a wide area south of the tropic from Chili across to Buenos Ayres. Though spread so widely over extra-tropical South America, it does not reach either the Cape or Australia, where the climate and soil seem so suitable for it. None of the single species have a very wide range, but it is one of the instances where a well-marked, sharply isolated generic type is represented in many different geographical areas by distinct specific types.

The present monograph is one of the best and most complete works of the kind that have lately appeared. It is extracted from the second part of the sixteenth volume of the *Denkschriften der Mathematisch-Naturwissenschäftlichen* class of the Kaiserlichen Akademie der Wissenschaften in Vienna. Dr. Stapf is one of the officials of the Botanic Garden of the University of Vienna, and has had the advantage of full command of material, both in the way of specimens and books. Two of the plates and a large proportion of the letterpress are devoted to the anatomy and morphology of the vegetative and reproductive organs of Ephedra. In the structure of the woody bundles Gnetaceæ establish some links of transition between Coniferæ and the typical Dicotyledons. Ephedra approximates in some points towards Casuarina. In the veining of its well-developed leaves Gnetum recedes from the ordinary Gymnospermous type. In Ephedra there is an unmistakable perianth to the male flower, but the homology of the outer wrapper of the seed is not so clear. Then follows the systematic portion of the monograph. Dr. Stapf admits twenty-eight certain and three imperfectly-known species, and for each of these he gives a diagnosis, a figure showing its essential characters, an extended description, and a full account of its synonymy and geographical distribution. He makes three sections, Alatæ, Asarea, and Pseudo-baccatæ, dependent mainly upon whether the seed is fleshy in a mature state, or dry and furnished with a wing. Then follows a list of local names, and a very full list of the books in which the genus is noticed, extending from Gerarde and Ray down to the present time. The monograph is one that deserves to be studied carefully, both by structural and systematic botanists.

J. G. B.

OUR BOOK SHELF.

Geological Mechanism; or, An Epitome of the History of the Earth. By J. Spottiswoode Wilson, C.E. (London and Manchester: John Heywood, 1890.)

THE nature of this little work of 135 pages will be best indicated by a brief statement of its contents. The book is divided into three portions of not very unequal length.

The first of these is "autobiographical," and relates, with much circumstance, the author's adventures at the Geological Society and Club, where, on the invitation of the late Sir Roderick Murchison, he read a paper in the year 1854. This is followed by an account (his own) of the causes which led to a disagreement between himself and the leaders of an exploring expedition of which he had been appointed a member. This part of the book is relieved from the charge of being prosaic, however, by the introduction of some very remarkable, and undoubtedly original verses.

Having devoted more than forty pages to himself, the author has left for the earth little more than fifty pages more; and in this space he contrives to dispose of a great number of highly important problems, beginning with "intelligence supreme; the nebular theory of Laplace; hypothesis of incandescence; theory of the crystalline rocks; hypothesis of metamorphism," &c.; and finishing up with "the lunar, magnetic, and solar tides; the progressive desiccation of the atmosphere and earth; the change of time; and the theory of creation."

Comprehensive as is this portion of the book, however, the author still finds much to put into his third part, or appendix—such as, "tails or atmospheres of planets and comets; the magnetic pole and change of climate; the magnetic tide of the atmosphere, &c." As in the first part he rose into poetry, here, in the appendix, he

soars into the realms of prophecy, and tells us about the climate which may be expected in these islands in the years 1970, 2020, and 2130!

The author assures us that he writes especially for civil engineers, and is not careful to conceal his contempt for "prominent men in other branches of science" and their opinions. But as there are some works "profitable for instruction," so there are others calculated to afford amusement; and it is very hard indeed that civil engineers should have a monopoly of all the fun that is to be got out of this one.

The Scenery of the Heavens. By J. E. Gore, F.R.A.S. (London: Roper and Drowley, 1890.)

THE title of this work is so suggestive of pictures that one cannot help feeling disappointed with the limited number of illustrations, especially as the book is designed for general readers. We look in vain, for example, for representations of Saturn and Mars, solar prominences, and many other celestial objects, of which no descriptions can convey so much to the mind as good illustrations. Some of the illustrations are reproduced more or less faithfully from photographs by Mr. Roberts and the Brothers Henry, but we regret to note that the wonderful photograph by Mr. Roberts of the Great Nebula in Orion is not amongst these. We may suggest also that in future editions some account be given of the instrument which reveals to us the greater part of the "scenery of the heavens."

On the whole, the text is excellent, and will no doubt greatly interest the general reader. There is, however, a very loose statement on p. 24—namely, "if we assume that the attraction of gravitation at the earth's equator is 32·2 feet, we have the accelerating force of gravity on the sun equal to 895 feet per second." One of the most notable features of the book is the large number of poetical selections having reference to astronomical phenomena. The book contains a good deal of information, in some cases perhaps too much to serve the avowed purpose of the author, unless his readers intend to become amateur observers. The long lists of red stars, doubles, variables, and star clusters, for example, are much too detailed for general readers, although not sufficiently so for regular observers. The chapter on variable stars, as might be expected from Mr. Gore, is especially good. There is also an excellent chapter on shooting-stars, by Mr. Denning, who is eminently fitted for such a task.

We may remind Mr. Gore that probably no one now supposes that the so-called "gaseous" nebulæ consist of nitrogen (pp. 197, 206), and that the structure of the Great Nebula in Andromeda as revealed in Mr. Roberts's photograph indicates that the nebula is probably not "a vast cluster of very small stars placed at an immense distance from the earth" (p. 204).

No attempt is made to touch upon any theoretical astronomy, and the scope of the book is therefore correctly described by the title.

A Trip through the Eastern Caucasus. By the Hon. John Abercromby. (London: Edward Stanford, 1889.)

IS it worth while for a traveller to make a six weeks' tour the subject of a book? Probably most people would answer promptly and emphatically, No; but any one who reads Mr. Abercromby's work will see that the reply may be wrong, and that everything depends on the nature of the scenes visited, and on the traveller's ability to give an account of his impressions. In the course of six weeks Mr. Abercromby twice crossed the main chain of the Caucasus by passes which are little used except by natives. He was fortunate enough to secure, through the instrumentality of Prince Dondukoff Korsakoff, the Governor-General of the Caucasus, a circular letter in Russian and Arabic to all in authority wherever he might wish to go. This, he says, acted like a charm, securing for him at every place the utmost hospitality. He had, therefore, the best possible opportunities of seeing what he desired to see, and of forming just opinions as to the characteristics of the people whom he visited.

Particularly good is his description of the strange village called Kubächi, in which there was at one time a flourishing school of the higher kinds of artistic craftsmanship. The village is "a long, narrow, extremely compact agglomeration of houses, built on the southern face of a very steep slope with a shallow ravine on both sides." A high round tower, commanding a wide view, stands at the top. All the roofs are flat, and, seen against the sky, the profile of the village is not unlike "a gigantic staircase." Before reaching Kubächi, Mr. Abercromby heard all sorts of wonderful stories about the inhabitants, and was assured that they were of Frankish origin. He found that there was nothing specially European-looking in the type of face either of the men or women. They appeared to him "quite like the Lesgians, though milder in their manners, and less wild-looking." Their speech has no sort of relation to the Indo-European languages, but belongs to the Lesgian family. There are in the village many sculptured stones and other relics of a period when the workers of Kubächi had a genuinely artistic impulse; and of these remains Mr. Abercromby gives a remarkably clear and attractive account. Not less interesting in its way is his description of the extraordinary wall of Derbend, which, according to the current native belief, is 3000 years old. For this idea there is of course no real foundation. Mr. Abercromby, with the enthusiasm of a thorough antiquary, investigated this structure with the greatest care, and even readers who are not generally attracted by archæological research will find much to please them in his narrative. Altogether, the work is fresh and bright, and we recommend it to the attention of those who find in good works of travel intellectual refreshment and stimulus.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Royal Society's Catalogue of Scientific Papers: a Suggested Subject-Index.

THE method advocated by Mr. J. C. McConnel (NATURE, February 13, p. 342) would undeniably be feasible. But I should pity the fellow-craftsman who should have to carry it out. The idea of numerical subdivision has been worked out by Prof. Dewey with great ingenuity and industry in his "Decimal Classification and Relative Index," 1885. We find, on referring to p. 31, that 016·9289551 will indicate the "Bibliography of Persian poets." Natural science occupies a place from 500–600, and does not seem to have been as yet reduced to an equal degree of elegant simplicity, for the subject of "observing chairs, &c.," is merely denoted by 522·28.

After this it does not seem over bold to pronounce the result one of the most amusing things in cataloguing literature. It is, however, surpassed by Mr. J. Schwartz's "King Aquila's Library," in which the system is fairly demolished. But the London inquirer into the actual working of such a cumbrous device may gain a useful hint by noting that at the Guildhall Library there is an alphabetical index to these totally unnecessary numbers. Indeed, one is found in Prof. Dewey's own book, and would, of course, be an absolute necessity in the proposed case.

No, a good subject-index can be constructed on much simpler lines. See, for example, Poole's "Index to Periodical Literature," which includes in its first supplement (1882-87) some 1090 volumes (indexed in 483 pages). Another example may be found in the subject-index at the end of the "List of Books of Reference in the British Museum Reading Room," 1889. In this some twenty thousand volumes are included, which would

lead one to suppose that the size Mr. McConnell suggests is ample, not to say generous. I had hitherto supposed that a scientific writer does not necessarily treat of a fresh subject each time he writes.

Might I add that an index is not a pedigree or diagram, any more than a gazetteer is the same thing as a map? I fear that to mix up such distinct things would merely introduce an altogether needless difficulty. A CATALOGUER.

The Period of the Long Sea-Waves of Krakatão.

IN connection with the great explosion at Krakatão at 10 a.m. on August 27, 1883, a great wave was generated, which at Batavia, 100 miles distant, reached a height of 7½ feet above the ordinary sea-level. It was followed by a fairly regular series of fourteen waves, at intervals of about two hours, gradually diminishing in height. Captain Wharton, who writes this part of the Royal Society Report, is much puzzled by the long period. He says:—"If the wave was caused by any sudden displacement of the water, as by the falling of large masses of ejected matter and huge fragments of the missing portion of Krakatão, or by the violent rush of steam from a submarine vent through the water, it is hardly to be conceived that two hours would elapse before the following wave, the second of the series, started after it. . . . If, however, upheaval of the bottom of the sea, more or less gradual, and lasting for about an hour, took place, we should have a steady long wave flowing away from the upheaved area, which as it approached the shore would be piled up considerably above its normal height. Thus these waves of long period would be set up. . . . The water would flow back on the motion ceasing."

I do not understand how the series of waves would be produced by the sea-bottom being upheaved in the manner described. When the upheaval ceased, the water would probably flow back, and, after the centre of disturbance was reached, a second wave would be generated. But there would be no reason for the water flowing back a second time, and no more waves would be generated. Further, in another part of the Report, we find Prof. Judd expressing the opinion that no upheaval has taken place (p. 25).

Another explanation has occurred to me, which seems satisfactory. Let us assume, with Prof. Judd, that the first wave was due to a great quantity of fragments falling into the sea. This wave would be reflected by the shores of the Straits several times backwards and forwards, each time giving rise to a fresh disturbance, travelling out towards Batavia through the narrow opening to the east. Opposite Krakatão both on the northern and on the southern shore of the Straits is a great bay. The time a wave would take to travel from Krakatão to the head of the bay on the north is given by Captain Wharton at sixty-one minutes, and the distance to the head of the other bay is much the same. This agrees very well with the two-hour period. Moreover the first disturbance at Batavia would be a rise of the water, which was the case.

In a similar way some of the short periods observed at distant stations may have been due to peculiarities of the channels in which the tide gauges were placed.

Hotel Buol, Davos. JAMES C. M. MCCONNEL.

The Distances of the Stars.

YOUR note of Prof. Eastman's address to the Philosophical Society of Washington in your columns of February 13 (p. 351) raises some questions of interest on which I think the Professor is mistaken.

As regards the nearness of particular stars, there are several indications which astronomers have sought to verify by observation and computation. One of these is brightness; a second is large proper motion, and a third is a binary system easily separated by the telescope (especially if the period is comparatively short). Some persons have also supposed that red stars, variable stars, &c., are nearer than most of their neighbours. Stars possessing one or more of these characteristics have been selected for parallax measurements.

One of these characteristics being brightness, almost every bright star in the northern hemisphere and a good many of those in the southern have been at one time or another measured for parallax. But no one has attempted to measure the parallax of *all* stars of the third, fourth, fifth, or sixth magnitudes. Astronomers have selected from among these stars those which afford some striking indication of nearness, such as the great proper motion of 61 Cygni. If, therefore, we take the parallaxes arrived at in this manner for comparison, we are comparing the results attained for *all* stars of the first magnitude with those attained for a small number of exceptional stars of the fifth or sixth.

How far Prof. Eastman's data are otherwise trustworthy I need not consider. I may refer your readers to a very full list of paraxalles hitherto determined, published by Mr. Herbert Sadler in the February number of *Knowledge*, by which it will appear how discordant and untrustworthy these results are. But the exceptional character of Prof. Eastman's faint stars is sufficiently evident from the table itself. His first group, with mean magnitude 5·57, has a mean proper motion of 4″·93; the second group, with a mean magnitude 5·59, has a mean proper motion 2″·33. Surely Prof. Eastman does not mean that the average proper motion of stars of the magnitude 5·58 is 3″·63. There is not one star in a hundred of this degree of faintness which possesses such a proper motion as this. W. H. S. MONCK.

Dublin, February 15.

P.S.—It is possible that a sphere enclosing the thirty nearest stars to us would include more faint stars than bright ones; but I think it certain that it would not include as large a percentage of fifth magnitude stars as of first magnitude stars. The first magnitude stars do not exceed twenty, and a few of them seem to be very distant. The fifth magnitude stars are reckoned by hundreds, and a few of them are comparatively near.

The Longevity of Textural Elements, particularly in Dentine and Bone.

WHATEVER views we may take of the theories of Weismann, which at present occupy the attention of biologists, they may be hailed as giving new directions to research, and one of the subjects about which his allusions will probably lead to further inquiry is the length of time during which textural elements continue individually. I have used the word longevity at the top of this letter; but, perfectly admitting the justice of Weismann's criticism—that division into two, each of which is a unity like the first, is not death—I feel driven to the dire necessity of inventing a new word, *permanunity*, to denote permanence without division; and it is of such permanence or longevity of the undivided unit that I wish to note a circumstance which has recently presented itself to my mind.

Every anatomist is aware that the living elements of dentine are nucleated corpuscles with elongated branches, which are embedded in the matrix, and lengthen as the dentine increases in thickness, while the corpuscles themselves retire inwards, remaining at the boundary of the lessening pulp-cavity. The continuity of the tubes containing these fibres furnishes, as soon as one thinks of it, convincing proof that they are the same branches and the same dentine-corpuscles which are found when the dentine begins to be deposited and when it is completed. But the dentine begins in childhood, and may go on increasing in thickness in old age, with its tubes still continuous, though losing their regularity of position. Therefore, dentine-corpuscles continue alive and without division through the greater part of the life of the organism.

The interest of this is exceedingly great, if the relation of dentine to bone be considered. Bone has a matrix similar to dentine, and has branched corpuscles; but the bone corpuscles differ from the dentine-corpuscles in becoming completely embedded in the mineralized matrix, without any attempt to retire from it, and thus come to have branches on every side. Under the microscope one can see in compact bony tissue that there is a continual reabsorption and redeposition of bone going on; and these alternating processes are brought about in a way which is easy to understand, though very generally misapprehended. In consequence, probably, of the very pressure exercised by the bony deposit on the corpuscles, the corpuscles are excited to absorb it; and one sees absorption spaces commencing sometimes in the centres of haversian systems, and sometimes in individual lacunæ. The activity thus aroused in the corpuscles causes them to enlarge and to attempt proliferation; which being in the first instance modified by their close surroundings leads to their being converted into large multinucleated masses, the so-called giant-cells or osteoclasts. But when a greater amount of room has been obtained, these masses separate up into corpuscles with one nucleus each, bone-corpuscles or osteoblasts, which, arraying themselves around the cavity, initiate the formation of new

concentric laminæ of bone. Thus it is certain that the permanunity of the bone-corpuscle is very inconsiderable indeed. It may be difficult to define it exactly, but a general consideration of the rapid changes in the shafts of young bones leads me to think it probably much less than a year.

There is thus a very surprising contrast between the undivided persistence or permanunity of a bone-corpuscle and that of a dentine-corpuscle, which is in various respects so similar to it. While there are numerous instances of very short-lived corpuscles in the body, I am not aware that until now proof has been offered of the persistence of any living tissue-elements throughout the life of the organism. JOHN CLELAND.

Some Notes on Dr. A. R. Wallace's "Darwinism."

I HAVE just read this most interesting work, "Darwinism"—seeming to me the clearest and most useful account of the Darwinian theory of evolution ever yet published—and while reading it I have made note of a few matters which I may, perhaps, be allowed to touch on here.

On p. 43 are quoted the numbers of varieties of the two snails, *Helix nemoralis* and *H. hortensis*, enumerated by a French author—no doubt Moquin-Tandon. These numbers, however, fall far below those actually known at the present day. These snails vary in many ways, but taking variations of *banding alone*, I know of 252 varieties of *H. nemoralis*, and 128 of *H. hortensis*.

To further illustrate the extreme variability of the Mollusca, take the varieties of land and freshwater Mollusca found in the British Islands. Of the 88 species of land shells we have 465 named varieties, and of the 46 species of British freshwater shells are 251 varieties. So that, excluding probable synonymy, we have about 5 named varieties in Britain to every species of inland mollusc.

In the same way, the numbers of *Rosa* and *Rubus* quoted on p. 77 are below the mark. Of *Rosa canina*, 33 varieties are known in the British Islands, while the British *Rubi* number 63 supposed species.

A good example of a species "occupying vacant places in nature" (p. 110), is afforded by the little mollusc *Cæcilianella acicula*, which is simply organized, and lives in great numbers underground (*vide Naturalist*, 1885, p. 321).

The true cause (as it seems to me) of the variability of freshwater species seems hardly indicated on p. 110. All freshwater productions, except those inhabiting large river basins (as the Mississippi), present these peculiarities—they are exceedingly variable and plastic, so that we get few but polymorphic species. Now, for the successful spread of freshwater organisms, it is necessary that they should be *plastic*, to adapt themselves to the new environment of every pond or river, and the varieties thus required must *not become fixed species*, because it is their very changeability under new environment that makes them successful in the struggle for existence and increase. Freshwater forms migrate more than is commonly supposed, and the contents of any pond or river are ever varying. Hence the necessities I have indicated. These points are exceptionally clear in the case of the *Unionidæ* of Europe and North America (see *Science Gossip*, 1888, pp. 182–184).

Colorado presents an exception to the rule (p. 112), that two species of *Aquilegia* are rarely found in the same area. In Colorado we have *five* columbines, viz. *A. formosa*, *A. chrysantha*, *A. brevistyla*, *A. cærulea*, and *A. canadensis*. But *A. cærulea* is the only one that can be called abundant.

On p. 139, it is stated that specific characters are essentially symmetrical. Yet the ocelli and spots on the butterflies of the families *Satyridæ* and *Lycænidæ* surely afford specific characters, and they are frequently asymmetrical (see *Entomologist*, 1889, p. 6).

On p. 151, we are told that in Ireland hardly one of the land molluscs has undergone the slightest change. This is not quite true, as the following forms seem to be peculiar to Ireland: *Arion ater* var. *fasciata*, *Geomalacus maculosus* vars. *allmani*, *verkruzeni*, and *andrewsi*, *Limax arborum* var. *maculata*, *L. arborum* var. *decipiens*, *Succinea vitrea* var. *aurea*, and *S. pfeifferi* var. *rufescens*. But these peculiar forms are not more numerous (but less so) than would be found in almost any continental area of equal size.

The theory (p. 206) that a recent change of food-plant has to do with the presence of green and brown varieties of the larva of *Macroglossa stellatarum* seems hardly tenable, as so many larvæ of different species and genera vary in the same manner.

I have thought (*Ent. Mo. Mag.*, 1889, p. 382) that asymmetrical variation in insects occurred most often on the left side. On p. 217 it appears that the same thing occurs in some Vertebrata.

On p. 230 the idea of environment directly influencing the prevalent colours of organisms is put aside as improbable. Yet it has seemed that moisture was the cause of a certain phase of melanism, especially among Lepidoptera. Evidence bearing on this point has been given during the last few years in the *Entomologist*.

The land shells on the small islands off the coast of Kerry, Ireland, are pale in colour, as I have recorded in Proc. South London Entom. and N.H. Soc. for 1887, pp. 97–98.

The point on p. 233, about the conspicuous colours of the Aculeate Hymenoptera, seems open to question. In temperate regions, at least, the *Aculeata* are mostly of very dull colours—as the *Andrenidæ*, many of the *Apidæ*, and hosts of others. Even the brilliant green *Agapostemon* flies among bright green foliage and yellow flowers, and is not very conspicuous when alive in its native haunts. On the other hand, the non-aculeate *Chrysididæ* and *Chalcididæ* are often exceedingly brilliant in colouring.

It seems quite doubtful whether the abundance and wide distribution of *Danais archippus* (p. 238) is due to immunity from parasites, &c., while its migratory habits are a quite sufficient explanation of the facts. Besides, it has at least one parasite—the *Pteromalus archippi*.

The "progressive change of colour" (p. 298) is well illustrated by the change from yellow to scarlet exhibited by so many groups of species. Scarlet species nearly always occasionally revert to yellow, and there are generally yellow species in the same genus. For details see Proc. South Lond. Ent. and N. H. Soc. for 1887.

Yellow flowers (see p. 316) seem the most attractive to insects in Colorado, and Mr. F. W. Anderson tells me that the same is the case in Montana. From reasons given in *Canadian Entomologist*, 1888, p. 176, I am of the opinion that insects cannot distinguish red from yellow.

It has seemed to me (see p. 359) that the agency of wind in distributing insects is greatly exaggerated. I believe whirlwinds may be most important as distributing agents, but ordinary gales less so. Many species of insects migrate, but usually *during calms*. Also (p. 360) the opinion that insects are often carried to the summits of mountains by winds seems to me without sufficient support. Many species of insects *live* only or habitually at high altitudes, and their presence there is no proof that they were carried there by winds, especially when they are specifically distinct from the species of lower regions. *Plusia gamma*, on the summit of Mont Blanc, is not very remarkable, as the moth is a great wanderer, and quite capable of finding its own way to high altitudes. Finally, I believe winds very rarely blow *up* mountain slopes. I have lived some time at the base of the great Sangre de Cristo Range in Colorado, and although violent winds blow *down* very frequently, I have *never observed an upward wind*, and residents whom I have questioned are unanimous in saying that they have never known a strong wind blow *up* the mountains. And the way the trees are bent and twisted at timber-line (11,500 feet), often with only branches on the side towards the valley, well indicates the direction of the winds.

I think, perhaps, the scarcity of Monocotyledons in the Rocky Mountains (p. 401) as compared with northern regions, is more apparent than real—the difference indicated in the books being due to the fact that the western grasses are not so well known as the eastern ones. Ferns are rarer on continents than on islands, and the dryness of the Rocky Mountain region is unfavourable to them.

A good instance of the effect of environment (see p. 419) recently came under my notice. The polymorphic snail *Helix nemoralis* was introduced from Europe into Lexington, Virginia, a few years ago. Under the new conditions it varied more than I have ever known it to do elsewhere, and up to the present date 125 varieties have been discovered there. *Of these, no less than 67 are new, and unknown in Europe, the native country of the species!* The variation is in the direction of division of the bands. An incomplete list of these varieties is given in *Nautilus*, 1889, pp. 73–77.

It seems doubtful (see p. 433) how far prickles are a protection from snails and slugs. I found prickles in the stomach of *Parmacella* (a slug), as recorded in *Journal of Conchology*, 1886, pp. 26–27.

It is a minor matter, but it seems a pity that the nomenclature of the species in a standard work like "Darwinism" should not be scrupulously exact. Thus (p. 17), "*Phalæna*" *graminis* should be *Charæas graminis*. "*Helisonia*" (p. 44) should be *Helisoma*, and it is only a section, or subgenus, of *Planorbis*. On p. 235, "*filipendula*" and "*jacobeæ*" should read *filipendulæ* and *jacobææ*. "*Sphinx fuciformis*," of Smith and Abbott (p. 203), is really *Hemaris diffinis*, while on p. 204, "*Sphinx*" *tersa* is a *Chærocampa*, and "*Sphinx pampinatrix*" is *Ampelophaga myron*. T. D. A. COCKERELL.

West Cliff, Custer Co., Colorado, January 22.

A Formula in the "Theory of Least Squares."

SOME time ago, having had occasion to investigate the relation between $\Sigma(x^2)$ and $\Sigma(v^2)$ in the "Theory of Least Squares," I found a simple formula which connects them, and which I have never seen given in any of the text-books on the subject. I inclose it, and hope it is worth publishing in your journal.

University of Toronto, February 1. W. J. LOUDON.

Let a number of observations be made on a quantity whose true value is T. If these observations be represented by M_1, M_2, M_3, . . . M_n, then the most probable value is A, the arithmetic mean, and $A = \frac{\Sigma(M)}{n}$. If, moreover, the true errors be denoted by x_1, x_2, x_3, . . . x_n, and the residuals by v_1, v_2, v_3, . . . v_n, then $\Sigma(v) = 0$ by the definition of the arithmetic mean. It is required to find a relation between $\Sigma(x^2)$ and $\Sigma(v^2)$. We have—

$$\begin{aligned} x_1 &= T - M_1 &\quad\text{and}\quad v_1 &= A - M_1 \\ x_2 &= T - M_2 & v_2 &= A - M_2 \\ x_3 &= T - M_3 & v_3 &= A - M_3 \\ &\text{\&c.,} & &\text{\&c.,} \end{aligned}$$

from which $\Sigma(v) = 0$.

∴ equating equal values of M_1, M_2, M_3, . . . , &c., we get—

$$\left.\begin{aligned} T - x_1 &= A - v_1 \\ T - x_2 &= A - v_2 \\ T - x_3 &= A - v_3 \\ &\text{\&c.} \end{aligned}\right\} \quad\text{or}\quad \begin{aligned} x_1 &= v_1 + T - A \\ x_2 &= v_2 + T - A \\ x_3 &= v_3 + T - A \\ &\vdots \end{aligned}$$

$$\begin{aligned} \text{and adding}\quad \Sigma(x) &= \Sigma(v) + n(T - A) \\ \text{and}\quad \Sigma(v) &= 0. \\ \therefore\quad \Sigma(x) &= n(T - A) \quad . \quad . \quad (1) \end{aligned}$$

Again—

$$\begin{aligned} x_1 &= v_1 + T - A \\ x_2 &= v_2 + T - A \\ &\text{\&c.} \end{aligned}$$

∴ squaring, we have—

$$\begin{aligned} x_1^2 &= v_1^2 + 2v_1(T - A) + (T - A)^2 \\ x_2^2 &= v_2^2 + 2v_2(T - A) + (T - A)^2 \\ x_3^2 &= v_3^2 + 2v_3(T - A) + (T - A)^2 \\ &\text{\&c.} \end{aligned}$$

$$\therefore \quad \Sigma(x^2) = \Sigma(v^2) + 2\{\Sigma(v)\}\{T - A\} + n(T - A)^2$$

But $\Sigma(v) = 0$; and from (1), $T - A = \frac{\Sigma(x)}{n}$;

$$\therefore \quad \Sigma(x^2) = \Sigma(v^2) + n\left\{\frac{\Sigma(x)}{n}\right\}^2$$

$$\Sigma(x^2) = \Sigma(v^2) + \frac{\{\Sigma(x)\}^2}{n}.$$

This is the exact formula; from which it may be seen that, as positive and negative errors are equally likely, a close approximation will be obtained by taking $\{\Sigma(x)\}^2 = \Sigma(x^2)$, neglecting $2\Sigma(xx^1)$.

And we obtain Gauss's formula—

$$\Sigma(x^2) = \Sigma(v^2) + \frac{\Sigma(x^2)}{n}, \quad\text{or}\quad \frac{\Sigma(x^2)}{n} = \frac{\Sigma(v^2)}{n - 1}.$$

Galls.

ADMITTING, with Prof. Romanes (NATURE, February 20, p. 369), the plausibility of Mr. Cockerell's view that galls may be attributed to natural selection acting on the plants directly, I beg leave to point out a very obvious difficulty—viz. the much greater facility afforded to the indirect action through insects, by the enormously more rapid succession of generations with the latter than with many of their vegetable hosts—oaks, above all.

Freiburg, Badenia, February 22. D. WETTERHAN.

The Cape "Weasel."

IN Prof. Moseley's account of his visit to the Cape of Good Hope ("Notes of a Naturalist on the *Challenger*," p. 153), the following sentence occurs:—"Again, there are tracks of the Ichneumon (*Herpestes*), called by some name sounding like 'moose haunt.'"

In Todd's "Johnson's Dictionary," 1827, we find: "*Mouse-hunt*, a kind of weasel;" two quotations being given:—(1) "You have been a mouse-hunt in your time" ("Romeo and Juliet," iv. 4). (2) "The ferrets and mouse-hunts of an index" (Milton, "Of Ref. in Engl.," B. 1).

Halliwell's "Dictionary of Archaic and Provincial Words" (1847) gives, on p. 564: "*Mouse hound, East.* A weasel." Halliwell denies the identity of this word with Shakespeare's mouse-hunt; and Nares ("Glossary") inclines to a similar view. But in any case it seems clear that Prof. Moseley's "moose-haunt" is a dialectical English form—mouse-hunt or mouse-hound; a general word for "weasel." E. B. TITCHENER.

3 Museum Terrace, Oxford, February 17.

The Chaffinch.

THE chaffinch sings almost throughout the year in this locality. The male bird never leaves us in winter like the female, and can be seen in large flocks daily. A singular circumstance that occurred here in December 1888 with regard to a chaffinch may be of interest. At one o'clock in the morning, during a gale, a chaffinch tapped at my study window. On this being opened, it flew into the room and roosted on a bookshelf; next morning it was liberated. This was repeated on two subsequent gales. Not only did it sing each time on being liberated, but all through the winter and spring it followed me about the garden, singing. E. J. LOWE.

Shirenewton Hall, near Chepstow, February 11.

ON THE NUMBER OF DUST PARTICLES IN THE ATMOSPHERE OF CERTAIN PLACES IN GREAT BRITAIN AND ON THE CONTINENT, WITH REMARKS ON THE RELATION BETWEEN THE AMOUNT OF DUST AND METEOROLOGICAL PHENOMENA.[1]

THE portable dust-counting apparatus, with which the observations given in the paper were taken, was shown to the meeting. The apparatus, which was described in a previous communication to the Society, is small and light. It is carried in a small sling-case measuring 8 × 5 × 3 inches. The stand on which it is supported when in use packs up, and forms, when capped with india-rubber ends, a handy walking stick, 1¼ inch in diameter and 3 feet long. No alterations have been made in the original design, and the silver mirrors which at first gave trouble and required frequent polishings, have been used every day for two or three weeks without requiring to be polished, when working in fairly pure country air.

With the paper is given a table containing the results of more than two hundred tests made with the apparatus. In addition to the number of dust particles there is entered in the table the temperature and humidity of the air, the direction and force of the wind, and the transparency of the air at the time.

The first series of observations were made at Hyères, a small town in the south of France, situated about 2 miles from the Mediterranean. The observations were made on the top of Finouillet, a hill about 1000 feet high. The number of particles on different days varied here from 3550 per c.c. to 25,000 per c.c., the latter number being observed when the wind was blowing direct from Toulon, which is distant about 9 miles.

Cannes was the next station, the observations being

[1] Abstract of Paper read before the Royal Society of Edinburgh on February 3. Communicated by permission of the Council of the Society.

made on the top of La Croix des Gardes. The number here varied from 1550 per cubic centimetre, when the wind was from the mountainous districts, to 150,000 when it came from the town.

At Mentone the number varied from 1200 per cubic centimetre in air from the hills to 7200 in the air coming from the direction of the town.

Tests were made of the air coming towards the shore from the Mediterranean at three different places—at La Plage, Cannes, and Mentone. In no case was the amount of dust small. The lowest was 1800 per cubic centimetre, and the highest 10,000 per cubic centimetre.

Observations were also made at Bellagio and Baveno, on the Italian lakes. At both stations the number was always great—generally from 3000 to 10,000 per cubic centimetre. This high number was owing to the wind, during the time of the observations, being light and southerly—that is, from the populous parts of the country. Smaller numbers were observed at the entrance to the Simplon Pass and at Locarno, at both of which places the wind blew from the mountains when the tests were being made.

A visit of some days was made to the Rigi Kulm. On the first day, which was May 21, the top of the mountain was in cloud, and the number of particles was as low as 210 per cubic centimetre. Next day the number gradually increased to a little over 2000 per cubic centimetre, after which the number gradually decreased till on the 25th the number was a little over 500 per cubic centimetre at 10 a.m. On descending the mountain to Vitznau the same day, the number was found to be about 600 per cubic centimetre at midday, and in the afternoon at a position about a mile up the lake from Lucerne the number was 650 per cubic centimetre.

Most of the observations taken of Swiss air show it to be comparatively free from dust. This is probably owing to the vast mountainous districts extending in many directions. It is thought that much of the clearness and brilliancy of the Swiss air is due to the small amount of dust in it.

Owing to the kindness of M. Eiffel an investigation of the air over Paris was made on the Tower on May 29. The day was cloudy and stormy, with southerly wind. Most of the observations were taken at the top of the Tower, above the upper platform, and just under the lantern for the electric light. The number of particles was found to vary very rapidly at this elevation, showing that the impure city air was very unequally diffused into the upper air, and that it rose in great masses into the purer air above. Between the hours of 10 a.m. and 1 p.m. the extreme numbers observed were 104,000 per cubic centimetre and 226 per cubic centimetre. This latter number was obtained while a rain-cloud was over the Tower, and, as the shower was local, the descending rain seems to have beaten down the city air. The low number continued some time, and was fairly constant during the time required for taking the ten tests of which the above low number is the average.

The air of Paris was tested at the level of the ground on the same day, the observations being made through the kindness of M. Mascart in the garden of the Meteorological Office in the Rue de l'Université. The number on this day varied from 210,000 to 160,000 per cubic centimetre.

Very few tests have been made of the air of London. The air coming from Battersea Park, when a fresh wind was blowing from the south-west, on June 1, was found to vary from 116,000 to 48,000 per cubic centimetre. The numbers observed in cities are of no great value, as so much depends on the immediate surroundings of the position where the tests are made; so that, while no ow number can be observed, a very high one can always be obtained. Those recorded were taken where it was thought the air was purest.

Observations have been made in Scotland for periods of two or three weeks at three stations—namely, at Kingairloch, which is situated on the shore of Loch Linnhe, and about fourteen miles to the north of Oban, at Alford in Aberdeenshire, the observations being made at a distance of two miles to the west of that village, and at a situation six miles north-west of Dumfries.

At Kingairloch the number varied from 205 per cubic centimetre to 4000 per cubic centimetre. At Alford from 530 to 5700 per cubic centimetre, and at Dumfries from 235 to 11,500 per cubic centimetre. These three stations were in fairly pure country air—that is, pure as regards pollution from the immediate surroundings.

Tests were also made of the air on the top of Ben Nevis on August 1, when the number was found to be 335 per cubic centimetre at 1 p.m., and 473 two hours later. On the top of Callievar, in Aberdeenshire, on September 9, the number was at first 262, and rose in two hours to 475 per cubic centimetre.

The pollution of the earth's atmosphere by human agencies is then considered, and it is pointed out that, while on the top of the Rigi and in the wilds of Argyllshire air was tested which had only a little over two hundred particles per cubic centimetre, near villages the number goes up to thousands, and in cities to hundreds of thousands. The increase, though great, is shown not to be in proportion to the sources of pollution, and it is pointed out that part of this is owing to the impure stream of air being deepened as well as made more impure.

About 200 particles per cubic centimetre is the lowest number yet observed, but we have no means of knowing whether this is the lowest possible, or of knowing how much of this is terrestrial and how much cosmic, formed by the millions of meteors which daily fall into our atmosphere. Even in the upper strata there seems to be dust, as clouds form at great elevations.

The effect of dust on the transparency of the atmosphere is then discussed with the aid of the figure in the table. It is shown that the transparency of the atmosphere depends on the amount of dust in it, and that the effect of the dust is modified by the humidity of the air. With much dust there is generally little transparency, but it is pointed out that air with even 5000 particles per c.c. may be clear, if it is so dry as to depress the wet-bulb thermometer 10° or more. By comparing days on which there was the same amount of dust, it is seen that the transparency varied with the humidity on two days with the same amount of dust; but the one with a wet-bulb depression of 13° was very clear, while the other, with a wet-bulb depression of only 2°, was very thick.

To show the effect of the number of particles on the transparency, a number of days are selected on which the humidity was the same, when it is seen that when the wet-bulb was depressed 4°, with 550 particles the air was clear, medium clear with 814, but thick with 1900. From the table a number of cases are taken illustrating the dependence of the transparency of the air on the number of particles in it, and on the humidity, both dust and humidity tending to decrease the transparency. Humidity alone seems to have no influence on the transparency apart from the dust, but it increases the effect of the dust by increasing the size of the particles.

The modifying effect of the humidity is shown to be influenced by the temperature. The same wet-bulb depression which will give with a given number of particles a thick air at a temperature of 60° will give a clearer air if the temperature be lower. This is illustrated by examples taken from the table. The increased thickening effect accompanying the higher temperature will be due to the increased vapour-pressure permitting the dust particles to attach more moisture to themselves. These remarks all refer to what takes place in what is called dry air—that is, air which gives a depression of the wet-bulb thermometer.

The conclusion come to from the consideration of all the observations is that the dust in the atmosphere begins to condense vapour long before the air is cooled to the dew-point. It seems probable that in all states of humidity the dust has some moisture attached to it, and that, as the humidity increases, the load of moisture increases with it.

Another method of testing the condensing power of dust for water-vapour is then described. In working this method the dust is collected on a glass mirror, and its condensing power is determined by placing the mirror over a cell in which water is circulated, in the manner of a Dines hygrometer. The temperature at which condensation takes place on the dust and on a cleaned part of the glass is observed. The difference in the two readings gives the condensing power of the dust. One kind of dust artificially prepared was found to condense vapour just at the dew-point, while another condensed it at a temperature 17° above the saturation-point. The atmospheric dust was collected on the mirrors on the same principle as that used in the thermic filter described by the author in a previous paper, the dust being deposited by difference of temperature, the necessary heat being obtained by fixing the collecting mirrors on a window-pane. Dust was also collected by allowing it to settle on the plates. The atmospheric dust was found to condense vapour at temperatures varying from 1°·8 to 4°·5 above the dew-point. This condensing power of dust explains why glass such as that in windows, picture frames, &c., often looks damp while the air is not saturated; and in part it explains why it is so necessary to keep electrical apparatus free from dust, if we wish to have good insulation.

The constitution of haze is then considered. It is shown that in many cases it is simply dust, on which there seems to be always more or less moisture. But as what is known as haze is generally seen in dry air, the effect is principally due to dust.

Some notes from the Rigi Kulm are given, where "glories" and coloured clouds were seen. The condition of the transparency of the lower air as seen from the top of the mountain is discussed with the aid of the observations made by observers at the lower levels. These observations were kindly supplied by M. Bilwiller, of the Swiss Meteorological Office. The difference observed at the top of the mountain in the transparency of the air in different directions is shown to have been caused by a difference in the humidity of the air in the different directions. The variation in the number of particles on the top of the mountain is considered, and it is shown that the great increase in the number which took place on the second day was probably due to the valley air being driven up the slopes, reasons being given for this supposition. The colouring in clouds, and on scenery at sunrise and sunset, as seen from the tops of mountains and valleys, is remarked upon, and it is shown that there is reason for supposing that when seen from the lower level the colours will generally be the more brilliant and varied.

The relation of the amount of dust to the barometric distribution is then investigated—as to whether cyclonic or anticyclonic areas have most dust in them. It is shown that there is most dust in the anticyclonic areas. The interpretation of this, however, is shown to be that the amount of dust depends on the amount of wind at the time, and as there is generally little wind in anticyclonic areas, there is generally much dust. Diagrams are given showing by means of curves the amount of dust on each day, and also the velocity of the wind. The curves are found to bear a close relation to each other—when the one rises the other falls. The only exceptions to this are when the stations where the observations were made are not equally surrounded in all directions by sources of pollution. In that case, even with little wind, if it blows from an unpolluted direction the amount of dust is not great.

The increase in the dust particles which takes place when the wind falls, seems to point to a probable increase of the infection germs in the atmosphere when the weather is calm. As, however, the conditions are not quite the same, the organic germs being much larger than most of the dust particles, and settling more quickly, it may be as well, while accepting the suggestion, to refrain from drawing any conclusion.

In all the fogs tested, the amount of dust has been found to be great. This is shown to be what might now be expected from a consideration of the conditions under which fogs are formed. One condition necessary for the formation of a fog is that the air be calm. But when the air is calm both dust and moisture tend to accumulate, and the dust, by increasing the radiating power of the air, soon lowers its temperature and causes it to condense vapour on the dust and form a fog. The thickness of a fog seems to depend in part on the amount of dust present, as town fogs, apart from their greater blackness, are also more dense than country ones. The greater amount of dust in city air, by increasing its radiating power, it is thought, may be the cause of the greater frequency of fogs in town than in country air.

At the end of the paper some relations are pointed out between the amount of dust and the temperature at the time the observations were made, showing that when there was a large amount of dust there was also a high temperature; and some speculations are entered into as to the effect of dust on climate. But it is at the same time pointed out that the observations are far too few and imperfect to form a foundation for any important conclusion on that subject.

In a short appendix is given the result of some tests made between January 23 and 29 of this year at Garelochead. During the gale on Saturday, the 25th, the number was rather under 1000 per cubic centimetre. On Monday, though the wind was still high, the number fell to about 250; and on Tuesday, when the wind had fallen and veered to the north, the number fell lower than had been previously observed. The number varied from a little over 100 to about 90 per cubic centimetre. On this day the air was remarkable for its clearness, the sun was very strong, and the evening set in with a sharp frost.

JOHN AITKEN.

P.S.—The author of the paper also showed at the same meeting of the Society the apparatus which have just been constructed from his designs for the Observatory on Ben Nevis. The apparatus has been constructed by the aid of a Government grant, obtained by the Council of the Scottish Meteorological Society, for the purpose of carrying on the investigation on the dust in the atmosphere at the top of Ben Nevis. Two complete sets of apparatus were shown. The one is the large laboratory form of the dust-counter, and is to be fixed, in the meantime, in the tower of the Observatory; the air being taken in to it by means of a pipe. The other is the small portable form of instrument, to be used when the direction of the wind is such as to bring the smoke of the Observatory towards the tower. This latter instrument has for a short time been in the hands of Mr. Rankin, one of the Ben Nevis observers, who has been practising with it near Edinburgh before beginning regular work at the Observatory.

A UNIFORM SYSTEM OF RUSSIAN TRANSLITERATION.

UP to the present time no one system of transliterating Russian names and titles into English has been generally adopted. Some of those most interested in the cataloguing and recording of Russian scientific literature have therefore arranged the following scheme in order to secure the general use of a system which will enable

those unacquainted with Russian, not only to transliterate from that language into English, but also to recover the original Russian spelling, and so to trace the words in a dictionary.

With reference to some of the letters a few words of explanation are necessary.

gh is adopted in preference to *g* for г, since this letter is also the equivalent of *h* in such words as Гидра, which, if transliterated *gīdra*, would lose its resemblance to the word *hydra*, with which it is identical.

Although і and и have the same sound, and with a few rare exceptions the letter used in the original may be recognized by a simple rule, it is recommended that the latter should be distinguished by the sign –, since the use of the same English symbol for two Russian characters is objectionable.

The semi-vowels, ъ and ь, must be indicated when present, except at the end of a word, by the sign ʻ placed above the line; otherwise, the transliteration of two Russian characters might give the same sequence as one of the compound equivalents, and it would become difficult to trace the words in a dictionary.

As regards the compound equivalents, nine out of the twelve may be at once recognized, since *h* must always be coupled with the preceding, and *y* with the succeeding, letter.

Where proper names have been Russianized, it is better whenever possible to use them in the original form rather than to re-transliterate them; there is no reason why *Wales* should be rendered *Uelʻs*, or *Wight* written as *Uait*. When a Russian name has a more familiar transliterated form, it is advisable to quote this as well as an exact transliteration with a cross reference.

The system will be adopted without delay in the following publications: the Catalogue of the Natural History Museum Library; the Zoological and Geological Records; the publications of the Royal Society, the Linnean, Zoological, and Agricultural Societies, and the Institution of Civil Engineers; the Mineralogical Magazine, and the Annals of Botany; and it is hoped that the system will be generally used.

An expression of grateful thanks is due to those who have assisted in the arrangement of this system by criticisms and suggestions; more especially to Madame de Novikoff and N. W. Tchakowsky.

The undersigned either accept the proposed system in the publications with which they are severally connected, or express their approval of the same:—

THE BOTANICAL INSTITUTE AND MARINE STATION AT KIEL.

PROF. J. REINKE contributes to the *Botanisches Centralblatt* a very interesting account of the Botanical Institute at Kiel, and of the Marine Station attached to it, as far as they are employed for botanical researches.

The harbour of Kiel is remarkably favourable for the observation of marine Algæ and the investigation of their life-history. In brown seaweeds the immediate neighbourhood is exceedingly rich, being scarcely inferior in the number of species to any other spot on the coasts of Europe. One important order, the Dictyotaceæ, is

altogether wanting; but another very interesting order, the Tilopterideæ, is well represented. In green Algæ, the large Siphoneæ of the Mediterranean and other warmer seas are represented only by *Bryopsis*. Of red Algæ, the number of species and genera is inferior to that found in the Mediterranean or on the coasts of England and France; but almost all the different types of growth are well represented. Although the Baltic has, like the Mediterranean, no tides, the sea-level of Kiel harbour falls so considerably with a south wind, that many littoral Algæ are then completely exposed.

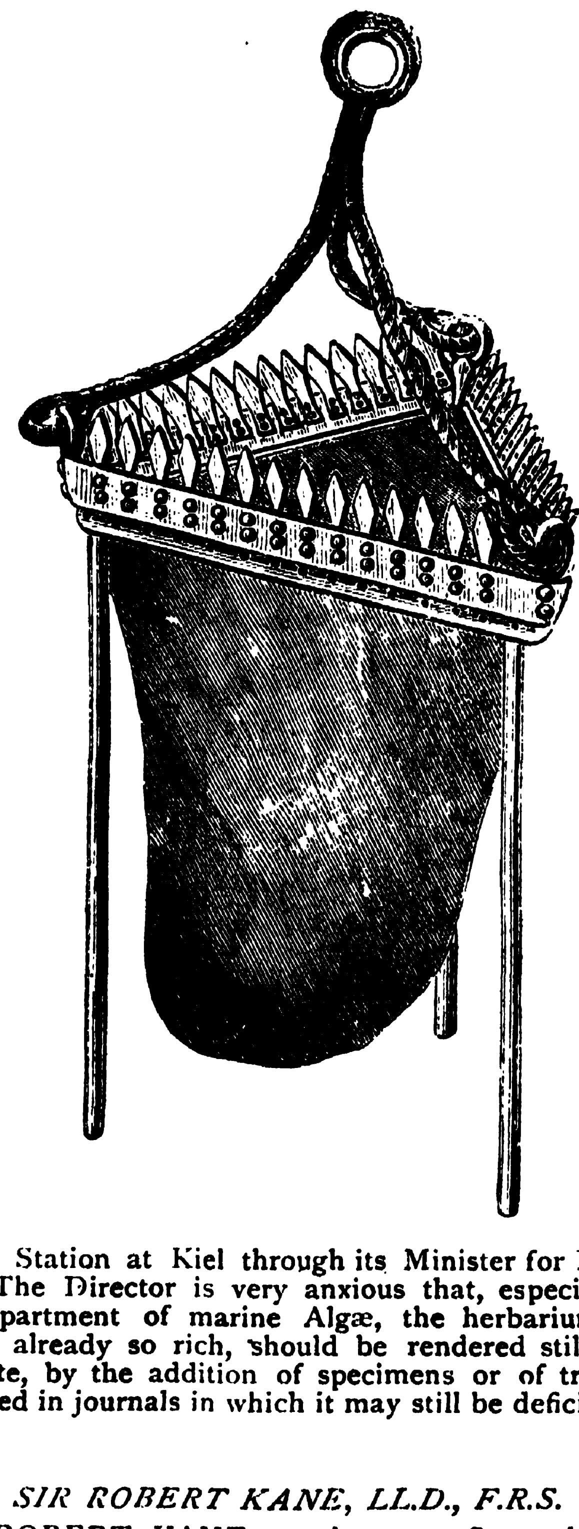
The growing-houses consist of a horse-shoe-shaped block of buildings, on one side of which is a long low house, and of a detached underground house. In designing the plan, the object specially kept in view was to furnish favourable conditions for the cultivation of all the important types of warmer climates; and the houses were therefore not built higher than seemed absolutely necessary. The chief part of the block consists of a higher and a lower cool-house, a higher and a lower hot-house, and a propagating-house. The higher houses are eight, the lower four metres in height, and the propagating-house still lower. Each of the lower houses is again divided into two, for different temperatures. The warmer division of the lower hot-house contains three basins for the culture of tropical fresh-water plants. The propagating-house is, in the same way, divided into two. The underground house is a long building entirely buried, the glass roof alone projecting above the surface of the ground. The heating is effected by hot-water pipes.

The various study-rooms are devoted partly to morphological and systematic, partly to physiological work. The former comprise a large herbarium in the top story, and four roomy work-rooms on the ground floor, in which are also kept those portions of the herbarium which are required for reference for the work in hand, and the whole of the dried Algæ. The first story is devoted to the residence of the Director. One of the work-rooms is devoted entirely to marine Algæ; each is fitted up with microscopical apparatus, and they are furnished with a very extensive reference-library. The second portion comprises a room with a small chamber opening out of it for chemico-physiological work: a room with stone floor, facing the north, for physico-physiological work; and a dark chamber with a balcony in the top story. Before the balcony a large sandstone slab is let into the wall of the building for the erection of a heliostat. In the basement story is a dynamo-machine.

For the collection of the seaweeds both row-boats and steamers are employed. For scraping the larger species off the rocks, Dr. Reinke has contrived a special drag-net, of which a drawing is appended, furnished with a row of sharp teeth at the mouth.

The culture of seaweeds presents greater difficulties in summer than in winter. They continue to grow in the Baltic at any temperature above zero C.; and, in cultivation, a low temperature is much more favourable to their growth than a high one. In the Institute they continue to fructify through the winter in the cool houses if protected from actual frost, the smaller species going through their complete cycle of development from the germinating spore; but a frequent change of the sea-water, or the addition of nutrient substances, is desirable. In summer the incidence of direct sunlight must be carefully avoided, and the temperature of the air must be kept as low as possible. For this purpose ice-cupboards have been built. Prof. Reinke has contrived a special arrangement for the cultivation of seaweeds in their native habitat. In the harbour near to the Botanic Garden, a wooden buoy is anchored, from which is suspended a wire basket by chains from 3 to 4 metres in length. In this floating aquarium the seaweeds grow exposed to their most favourable natural conditions of currents and variations of temperature in the water during the summer months. Next spring it is proposed to build an aquarium for seaweeds for public exhibition in connection with the Institute.

The Government of Prussia has rendered great assistance in the establishment of the Botanical Institute and



Marine Station at Kiel through its Minister for Education. The Director is very anxious that, especially in the department of marine Algæ, the herbarium and library, already so rich, should be rendered still more complete, by the addition of specimens or of treatises published in journals in which it may still be deficient.

SIR ROBERT KANE, LL.D., F.R.S.

SIR ROBERT KANE was born on September 24, 1810, in Dublin. This was the fiftieth year of King George III. and the tenth of the Union. Shortly afterwards his father established chemical works on the North Wall, by the side of the River Liffey, which in time developed into important and well-known sulphuric acid and alkali works. His mother was Ellen Troy, of whose family Dr. Troy, Roman Catholic Archbishop of Dublin, was a member. Sir Robert Kane very early in his life developed a taste for chemical knowledge, and in 1828 his first paper, "On the Existence of Chlorine in the Native Peroxide of Manganese," was published, and followed by a series of contributions on kindred themes. He entered Trinity College, Dublin, in 1829, and pro-

ceeded to his B.A. degree in the spring commencements of 1835, taking the LL.D. in the summer of 1868. In 1834 he was appointed Professor of Natural Philosophy to the Dublin (now the Royal Dublin) Society, and he at this period devoted himself with great ardour to original research in the field of chemistry, as the long list of his papers in the Royal Society's list will testify. He studied in Germany during his summer vacations under both Liebig and Mitscherlich, and passed some time under Dumas at Paris. In 1831 he was elected a member of the Royal Irish Academy; he was Secretary of its Council from 1842 to 1846, and was elected President in 1877. In 1849 he was made a Fellow of the Royal Society; shortly afterwards he was selected by the Government as head of the Museum of Irish Industry, which post he held until appointed the first President of the Queen's College, Cork. He was a Fellow of the King and Queen's College of Physicians, Ireland, a Commissioner of National Education, and a Justice of the Peace, Ireland.

After over twenty-two years of hard and earnest work in the development of the Cork College, he resigned the presidency in 1873, and took up his residence in Dublin, where he died on Sunday, the 16th instant.

Sir Robert Kane, in addition to the very numerous papers above referred to, was the author of a large and most important work on the industrial resources of Ireland, a theme which he handled in a painstaking and judicious manner. In his very early days he had acquired a practical knowledge of the value and importance of many of the neglected industries of Ireland, and from his chair in the lecture theatre of the Dublin Society, he often called attention to this subject, one which throughout his long life he never lost sight of. It is not without interest to note the fact that much is owing to the Royal Dublin Society for the ready help afforded to their two Professors, now both deceased, Sir Richard Griffith and Sir Robert Kane, in their efforts to advance the industries of Ireland.

In 1841, Sir R. Kane was awarded by the Royal Society a Royal Medal for his researches into the chemical history of archil and litmus; and in 1843, the Cunningham Gold Medal of the Royal Irish Academy, for his researches on the nature and constitution of the compounds of ammonia. These memoirs will be found published in the Transactions of the respective institutions.

In recognition of his scientific labours, and on his appointment to the presidency of Queen's College, Cork, he received knighthood in 1846 from Lord Heytesbury, the then Irish Viceroy. On the passing of Mr. Fawcett's Act in 1875, which altered the constitution of the University of Dublin, and appointed a Council, Sir Robert Kane was elected one of the first Roman Catholic members of that body, a post which he held until 1885, when the late Dr. Maguire was elected.

In this brief obituary notice, it is not necessary to attempt any analysis of the scientific work accomplished by Sir Robert Kane, but it is impossible to conclude it without a tribute of respect and affection to the many high and excellent qualities of the man, who in the various positions of Professor, head of a young educational establishment, or President of an Academy, won equally, from all with whom he came in contact, regard and esteem.

NOTES.

PROF. SCHUSTER has been elected Bakerian Lecturer for the present year. The lecture is to be delivered in the apartments of the Royal Society on March 20.

LAST week Mr. Justice Kay complained that judicial time is sadly wasted over patent cases, and he declared that the smaller and more petty the dispute the more time seemed to be expended. Now, as we have pointed out more than once, enormous waste of time is inevitable where the suitors in patent cases, especially in cases which involve scientific details, as most of them do at the present day, have to appear before a judge who is not himself a man of science. They have to begin by teaching his lordship the rudiments of that branch of science of which the disputed patent is a practical application. That our judges are painstaking, rapid, and acute pupils may readily be granted, but still time has to be consumed in the task, and there is something pathetic in the spectacle of an able and conscientious lawyer wrestling with the problems presented by the highest applications of, say, electricity or chemistry to industry, while scientific witnesses are contradicting each other all round him. We fear that judicial time will continue to be wasted so long as judges without a knowledge of science are left unaided to decide questions which demand long scientific training. There can be no change for the better until judges have sitting on the bench with them scientific assessors as they have now nava assessors, or until scientific cases are passed on as a matter of course to qualified referees as cases involving accounts are. It requires at least as much special training, and is as far outside the experience of ordinary lawyers, to settle a scientific case, as to decide whether a ship has been properly navigated, or whether a set of accounts tell in favour of a plaintiff or a defendant.

ON Tuesday evening there was some discussion in the House of Commons as to the supplemental vote of £100,000 for the purchase of a site at South Kensington for a suitable building for the housing of the science collections. Mr. Jackson explained that the extent of the land was four and a half acres, and the sum at which it was valued included a building for which the Government now paid a rent of £1500 a year, which would, of course, fall out of the Estimates when the Government became the proprietors of the land in question. No commission was to be paid to any person on either side in respect of this transaction, which was a direct one between the Commissioners of the 1851 Exhibition and the Government. Sir H. Roscoe thought it desirable that the money should be voted at once. The plot of land was the only one ever likely to be available for the purpose. Mr. Mundella said that as he had been pressing upon Governments for the last ten years the necessity for them to acquire this land, he thought that he ought to say something in defence of what the Government had done in asking for the sum on the present occasion. He did not approve of supplementary estimates, and he thought that no one would be more glad to get rid of them than the Government themselves. This question, however, had been pressing for the last ten years, because for the whole of that period the most valuable national science collections, such as no other country in the world possessed, had been housed in the most disgraceful manner. The Treasury had all along resisted the demands made upon them to sanction the expenditure necessary for the erection of a Museum to hold these collections, notwithstanding that three departmental committees had reported in favour of that expenditure. The only question, therefore, was whether the Government were getting good value for their money in making this purchase. He knew something of the value of the land, which had been fixed by eminent surveyors at £200,000, while the Government were going to get it for £70,000. The money which the Commissioners would receive in respect of the sale would be appropriated to providing scholarships for the promotion of technical education to the amount of £5000 per annum, which were to be open to all schools of every denomination in the United Kingdom. He therefore urged the Committee to agree to this proposal at once. Sir L. Playfair explained that the Commissioners of the Exhibition of 1851 had formed their estimate of

the value of the land upon the value of the surrounding property. The Commissioners had been pressed year after year to apply their surplus revenues to educational purposes. They had pressed the Government to come to some conclusion on the subject, as it had been going on for from three to ten years. They could not go on waiting continually, and the Government at last came to the conclusion—and, he thought, came to a wise conclusion—to accept the offer. He thought the Committee would see that they had been very patient. Mr. W. H. Smith, replying to the objection that the vote ought to have been included in the ordinary estimates, pointed out that if the vote were not taken at once, probably it could not be reached before June or July, or even August. It was unreasonable to ask the Commissioners to wait until that time. He had resisted the expenditure at South Kensington as long as he could, and until he was satisfied that in the interests of the country it was necessary. He strongly resisted the expenditure before, but when the Committee they had appointed reported that further accommodation was required, they had no alternative but to carry out their recommendations. The proposal of the Government was accepted by a majority of 77—the number of those in favour of the reduction of the vote being 67, while 144 voted on the other side.

We regret to notice the death, on February 2, of M. Ch. Fievez, the assistant in charge of the spectroscopic department of the Royal Observatory of Brussels, at the comparatively early age of 45. M. Fievez did not enter the Observatory until 1877, having been originally intended for the military profession. M. Houzeau, then the Director of the Observatory, being desirous of creating a spectroscopic department, sent Fievez, to whom he proposed to commit its management, to study under Janssen at Meudon, with whom he remained six months. Fievez's most important work was the construction of a chart of the solar spectrum on a scale considerably greater than that of Ångström; but besides this he was not able to effect much in astronomical spectroscopy, owing to the unfavourable position of the Observatory for such observations. He therefore turned his attention principally to laboratory work, and in this department made a detailed study of the spectrum of carbon, besides numerous experiments on the behaviour of spectral lines under the influences of magnetism and of changes of temperature. M. Fievez was Correspondant of the Royal Academy of Belgium, and Foreign Member of the Society of Italian Spectroscopists.

Students of palæontology heard with much regret of the recent death of Prof. von Quenstedt, of Tübingen. He was the most famous of German palæontologists, and did much important work in mineralogy also. He had an especially profound knowledge of the Lias of Würtemberg and its fossils. His work on "Der Jura" is well known, and so recently as 1885 a new edition, greatly modified, of his "Handbuch der Petrefactenkunde" was issued. Dr. von Quenstedt died at an advanced age on December 21, 1889.

A writer who is contributing to *Industries* a series of articles on the "Recent Growth of Technical Societies," infers, from a comparison of the balance-sheet for 1878 with that for 1888, that the Proceedings of the Royal Society are "evidently less sought after than they were." An average of four years would have pointed to an opposite conclusion. For the years 1876–79 the average sale was £743 1*s.* 7*d.*, while that of 1886–89 was £810 3*s.* 3*d.* The writer leaves out of account, moreover, that in 1878 the Royal Society, according to their published list, presented their Transactions and Proceedings to 276 institutions, while at present they give them to no fewer than 363 institutions.

Much interest has been excited by the announcement of the discovery of coal in Kent. The search for coal at a point near the South-Eastern Railway, adjoining the experimental heading for the Channel Tunnel, has been carried on for several years. The following report, by Mr. Francis Brady, C.E., the engineer-in-chief of the South-Eastern and Channel Tunnel Companies, was published in the daily papers on February 20:—"Coal was reached on Saturday last, the 15th inst., at 1180 feet below the surface. It came up mixed with clay, and reduced almost to powder by the boring tools. A small quantity of clean bright coal found in the clay was tested by burning, and proved to be of good bituminous character. The seam was struck after passing through 20 feet of clays, grits, and blackish shales belonging to the coal-measures, which at this point lie close under the Lias, there being only a few intervening beds of sand, limestone, and black clay separating them. The correspondence of the deposits with those found in the Somersetshire coal-field is thus pretty close, the difference consisting in the absence of the red marl at the Shakespeare boring. The lines of bedding in the shale are distinctly horizontal. This is an indication that the coal-measures will probably be found at a reasonable depth along the South-Eastern Railway to the westward. I beg to hand you herewith two specimens of the clay containing coal, one taken at 1180 feet, and the other at 1182 feet. I also inclose a specimen of clean coal taken to-day at 1183 feet 6 inches from the surface." With regard to this report, Prof. Boyd Dawkins writes to us:—"As the enterprise resulting in the discovery of coal near Dover was begun in 1886, and is now being carried on under my advice, I write, after an examination of the specimens from the boring, to confirm the published report of Mr. Brady, so far as relates to the coal. The coal-measures with good blazing coal have been struck at a depth of 1160 feet, well within the practical mining limit, and the question is definitely answered which has vexed geologists for more than thirty years. Further explorations, however, now under consideration, will be necessary before the thickness of the coal and the number of the seams can be ascertained. This discovery, I may add, with all the important consequences which it may involve, is mainly due to the indomitable energy of Sir Edward W. Watkin."

The second meeting of the Australasian Association for the Advancement of Science seems to have been in every way most successful. It was held at Melbourne, and began on January 7. At the Sydney meeting last year there were 850 members. This year the number rose to 1060. Baron von Müller, F.R.S., was the President. Great efforts were made to secure that members from a distance should enjoy their visit to Melbourne, and the serious work of the various Sections was varied by pleasant excursions. An excellent "Hand-book of Melbourne," edited by Prof. Baldwin Spencer, was issued.

This year the University of Helsingfors will celebrate its two hundred and fiftieth anniversary. It was founded at Abo, but transferred to Helsingfors in 1820.

At a recent meeting of the French Meteorological Society, M. Wada, of the Tokio Observatory, gave a *résumé* of the seismological observations made in Japan during 1887. The number of earthquake shocks amounted during the year to 483. The hourly and monthly distribution of the shocks at Tokio during the last 12 years shows a slight excess in favour of the night-time, above the day; and also an excess in winter and spring, over the other seasons. The area affected during the year 1887 represented five times the superficies of the empire. M. Wada gave details of the shocks, their direction, intensity, and distribution.

Tidings of another great volcanic eruption have come from Japan. Mount Zoo, near the town of Fukuyama, in the Bingo district, began to rumble at 8 o'clock on the evening of January 16, and the top of the mountain is said to have been soon "lifted off." There was a din like a dynamite explosion, and

sand and stones were belched forth. Stones and earth also fell at Midsunomimura, a village six miles away. No previous eruption of Mount Zoo is recorded. Only one man lost his life, but some cattle were killed, and 55 houses were destroyed. The total loss entailed by the eruption is estimated at nearly $3,500,000.

TWO rather strong shocks of earthquake were felt at Rome on Sunday last, February 23, shortly after 11 p.m. They were more distinct in the environs than in the city itself, and especially at the Rocca di Papa in the Campagna. The Rome correspondent of the *Daily News* says it was remarked that flocks of sheep "showed great signs of fear some time before the shocks were felt." The correspondent of the *Standard* notes that in several public buildings the gas was almost extinguished, that electrical apparatus was disturbed, and that electric bells were set ringing. "My own experience," he adds, "was that of feeling lifted up from my seat, and then set down again with a slight, but sickening, jar, while doors rattled, and furniture was moved so as to produce noise in knocking against walls."

ACCORDING to a telegram sent through Reuter's agency from Lisbon, a slight shock of earthquake was felt on February 24 at Leiria and places between it and the sea coast.

THE Pilot Chart of the North Atlantic Ocean for February states that the month of January was remarkable for the tempestuous weather that prevailed almost uninterruptedly over the steamship routes. Storms succeeded each other in rapid succession, the majority of them having developed inland and moved east-north-east on very similar paths from Nova Scotia and across southern Newfoundland. The most notable storm of the month was probably one that developed in the St. Lawrence valley, and crossed the Straits of Belle Isle early on the 3rd. It then moved nearly due east, rapidly increasing in intensity until reaching the 20th meridian, when it curved to the north-eastward, and was central on the 5th about lat. 55° N., long. 17° W., and disappeared north of Scotland. The barometric pressure in this storm was remarkably low, 27·93 inches having been recorded at 4 p.m. on January 4, about lat. 53° N., long. 23° W. There was a slight increase in the amount of fog experienced; it was confined for the most part to the regions west of the Grand Banks. Much ice has been reported since the 5th; the positions and dates plotted on the chart indicate that the ice season is one of the earliest on record—nearly a month earlier than usual. This is due in a great measure to the prevalence of severe northerly gales east of Labrador, coincident with the heavy westerly gales of December and January along the Transatlantic route.

THE Japanese Government, we observe, is about to establish a meteorological observatory in the Loochoo Islands. This is one of the most important positions in the East for meteorological purposes, for it fills up the very large gap at present existing between Shanghai and Manilla in one direction, and Hong Kong and Tokio in the other. Besides, the Loochoo Archipelago is a specially valuable position for observing the phenomena connected with the course of the typhoons of the China seas.

THE meeting of the International Congress of Hygiene and Demography, which is to be held in London in 1891, will probably be thoroughly successful. An organizing committee, with Sir Douglas Galton as President, has been formed, and already delegates have been appointed by the leading scientific societies. On Tuesday, February 18, a deputation waited upon the Lord Mayor to discuss the arrangements that ought to be made for the meeting. The Lord Mayor, having heard what Sir Douglas Galton, Prof. Corfield, and other members of the deputation had to say as to the importance of the Congress, undertook that the matter should be brought forward at a public meeting in the Mansion House. This meeting will take place on Thursday, April 24, and the Lord Mayor will preside.

THE ninth annual meeting of the members of the Sanitary Assurance Association was held on Monday, February 17, Sir Joseph Fayrer, F.R.S., in the chair. Mr. Joseph Hadley, Secretary, read the annual report, which concluded as follows:— "Though the important bearing of the work of the Association on the public health is not yet fully appreciated by the general public, the financial statement for the past year proves that the Association is making progress, and that after nine years' experience its work continues to be appreciated. The income for the year was £398 8*s.* 10*d.*, and after meeting all liabilities a balance is carried forward." The Chairman, in proposing the adoption of the report, said that the more he saw of the work of the Association, and the need for sanitary improvement, the more was he interested in its progress, and he expressed a hope that not only might this Association prosper, but that others might be formed, so great was the work to be done. General Burne and Dr. Danford Thomas were re-elected members of the executive council, and Sir Joseph Fayrer and Prof. T. Roger Smith were re-elected President and Vice-President respectively.

SOME time ago we referred to the fact that the Manchester Field Naturalists' and Archæologists' Society had appointed a committee for the purpose of promoting the planting of trees and shrubs in Manchester and its immediate suburbs. The idea has commended itself to the Corporation, and it is expected that evergreen shrubs, planted in boxes or tubs, will soon be placed in some of the principal squares. Meanwhile, the committee are trying to obtain the aid of experienced practical men. They have issued a circular with the following list of questions:— "What description of trees would you especially recommend for open spaces?" "What kind of shrubs, especially such as would succeed in tubs or boxes?" "What suggestions can you offer as to soil, treatment, and upon any important point relating to tree culture in towns?" When the best information that can be obtained has been brought together, it will be embodied in a pamphlet, which may, it is hoped, serve as a general guide for tree planting and culture.

AT the meeting of the Royal Botanic Society on Saturday, the Secretary called attention to several plants of hygrometric club moss from Mexico, which had been presented, with other specimens, by Mr. A. Gudgeon. The Secretary stated that these plants had the power, ascribed to the well-known rose of Jericho, of rolling themselves up like a ball when dry, and becoming apparently dead; but that they were able to unfold and grow again when exposed to moisture. The specimens shown had been kept for three months in a dry place, but now were green, and to all appearance flourishing.

THE following lectures will be given at the Royal Victoria Hall during March:—March 4, Mr. F. W. Rudler, on "Geology in the Streets of London"; 11th, Dr. Dallinger, on "The Infinitely Great and the Infinitely Small"; 18th, Prof. Beare, on "Australia"; 25th, Mr. W. North, on "Rome."

"OUR Earth and its Story" (Cassell and Co.) consists of three volumes, not two, as inadvertently stated in our notice of the work on February 13 (p. 341).

A SERIES of new compounds of hydroxylamine, NH_2OH, with several metallic chlorides, are described by M. Crismer in the current number of the *Bulletin de la Société Chimique*. The first member of the series obtained was the zinc compound $ZnCl_2.2NH_2OH$, whose existence was unexpectedly discovered during the course of experiments upon the action of metallic zinc on aqueous hydroxylamine hydrochloride. A ten per cent. solution of this latter salt was treated with an excess of pure zinc; no evolution of gas was noticed in the cold, but on warming

over a water-bath a slow disengagement of bubbles was found to occur. After allowing the reaction to complete itself during the course of a few days, the liquid, which had become turbid, was filtered, allowed to cool, and again filtered from a little more flocculent material which separated out, and finally concentrated and allowed to crystallize. A large quantity of hemispherical crystal aggregates then separated, which were found on analysis to consist of the new salt, $ZnCl_2.2NH_2OH$. Several other methods of obtaining it were investigated; it may be obtained by treating an aqueous solution of hydroxylamine hydrochloride, $NH_2OH.HCl$, with zinc oxide or carbonate, or with a mixture of zinc sulphate and barium carbonate, or by treating an alcoholic solution of hydroxylamine with zinc chloride. But the best method, and one which gives 97 per cent. yield, consists in dissolving ten parts of hydroxylamine hydrochloride in 300 c.c. of alcohol in a flask provided with an inverted condenser; the liquid is then heated to the boiling-point and five parts of zinc oxide added, the boiling being continued for several minutes afterwards. The clear liquid is then decanted and allowed to cool. After the deposition of the first crop of crystals, the mother liquor may be returned to the flask and treated with a further quantity of zinc oxide, four repetitions of this treatment being sufficient to obtain an almost theoretical yield of the salt. The white crystals are then washed with alcohol and dried in the air. They resist the action of most solvents, water only slightly dissolving them, and that with decomposition. Organic solvents are practically without action upon them. When heated in a narrow tube, as in attempting to determine the melting-point, the salt violently explodes. If a quantity is heated to about 120° C., in a flask connected with a couple of U-tubes, the second containing a little water, gas is abundantly liberated, and drops of hydroxylamine condense in the first U-tube together with a little nitrous acid. The water in the second tube is found to contain hydroxylamine, ammonia, and nitrous acid, while fused zinc chloride remains behind in the flask. A similar cadmium salt was also obtained, $CdCl_2.2NH_2OH$, in brilliant crystals which separated much more quickly than those of the zinc salt. This cadmium compound is much more stable under the action of heat, gas being only liberated in the neighbourhood of 190°-200°, and only a little hydroxylamine distils over. The barium salt, $BaCl_2.2NH_2OH$, is a specially beautiful substance, crystallizing from water in large tabular prisms, which are very much more soluble in water than either of the salts above described.

THE additions to the Zoological Society's Gardens during the past week include an Esquimaux Dog (*Canis familiaris* ♀), bred in England, presented by Mr. W. Tournay; two Barbary Turtle-Doves (*Turtur risorius*) from North Africa, presented by Miss Teil; a Bonnet Monkey (*Macacus sinicus* ♀), a Macaque Monkey (*Macacus cynomolgus* ♂) from India, a Common Raccoon (*Procyon lotor*) from North America, deposited; a Green Monkey (*Cercopithecus callitrichus*) born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on February 27 = 8h. 30m. 43s.

Remarks.

(1) "Very bright; very large; at first very gradually, then very suddenly much brighter in the middle." The spectrum of this nebula has not yet, so far as I know, been recorded.

(2) Dunér classes this with stars of Group II., but states that the spectrum is very feebly developed, and expresses a doubt as to the type. As I have before remarked, Mr. Lockyer's discussion of the stars of this group seems to indicate that the spectra which are described as "feebly developed" really represent stages in the passage from one group to another. If, for example, we consider a rather faint star with the banded spectrum a little more developed than in the case of Aldebaran, its spectrum would no doubt be described as "feebly developed," if classed with Group II. In such a case the star would be more condensed than those in which the spectrum is said to be well developed, and the flutings would have almost entirely given way to lines. Line absorptions would therefore indicate that the star belonged to a late stage of the group. On the other hand, if the star be at a very early stage of condensation, the flutings would still only be feebly developed, and might be accompanied by bright lines. In any case, further examination is necessary, as the star may belong to an early stage of Group VI., and not to Group II. at all.

(3) A star classed by Vogel with stars of the solar type. The usual differential observations are required.

(4) A star of Group IV. (Vogel). The usual observations are required.

(5) A "superb" example of stars of Group VI. (Dunér). The principal bands are very wide and dark, and the secondary bands 4 and 5 are also well seen. Bands 7 and 8 are doubtful.

(6) This variable will reach a maximum about March 7. The period is about 360 days, and the magnitudes at maximum and minimum are 8·2 ± and < 13 respectively. The star is not included in Dunér's catalogue, but Vogel states that the spectrum is of the Group II. type. Observations before and after maximum, with special references to changes of spectrum, should be made.

NOTE ON THE ZODIACAL LIGHT.—In favourable localities the zodiacal light should now be visible in the evening, and as further spectroscopic observations are desirable, it may be convenient to briefly summarize here the results already obtained. Ångström first observed the spectrum at Upsala, in March 1867, and noted the presence of the chief line of the aurora spectrum, at a wave-length stated as 5567. Respighi, in 1872, also observed this line, in addition to a faint continuous spectrum, and believed this to demonstrate the identity of the aurora and zodiacal light. He found, however, that at the same time the bright line was visible in almost every part of the sky, and this led to the suggestion that it originated from a concealed aurora. Prof. Piazzi Smyth, in Italy, observed nothing but a faint continuous spectrum, extending from about midway between D and E to F. A. W. Wright's observations led him to the following conclusions:—"(1) The spectrum of the zodiacal light is continuous, and is sensibly the same as that of faint sunlight or twilight. (2) No bright line or band can be recognized as belonging to this spectrum. (3) There is no evidence of any connection between the zodiacal light and the Polar aurora" (Capron's "Auroræ," p. 69). Mr. Lockyer believes the zodiacal light to be due to meteoritic dust, which is to a certain extent self-luminous, as indicated by the bright line in the spectrum, and argues in favour of a connection between auroræ and the zodiacal light (Proc. Roy. Soc., vol. 45, p. 247). He says:—"The observations of Wright and others, showing that the spectrum is continuous, are not at variance with Ångström's observation, for we should expect the spectrum to be somewhat variable. It is probable that the observations showing nothing but continuous spectrum were made when the temperature was only sufficient to render the meteoritic particles red hot. That the zodiacal light does consist of solid particles, or, at all events, of particles capable of reflecting light, is shown by the polariscope." He also quotes from a letter in which Mr. Sherman, of Yale College, states that he has reason to believe that the appearance of the bright line in the zodiacal light has a regular period.

On January 20 I saw the zodiacal light very well at Westgate-on-Sea, but was unable to detect anything beyond a faint continuous spectrum.

Mr. Maxwell Hall's observations at Jamaica (see NATURE, February 13, p. 351) also record continuous spectra, but with remarkable changes in the region of maximum intensity. He suggests comparative observations with the spectrum of twilight.

In connection with the suggestion of the variability of the spectrum, it is important to secure further observations. If the existence of the bright line at some periods be established, we may then safely conclude that the luminosity of the zodiacal light is not entirely due to reflected sunlight.

A. FOWLER.

OBSERVATIONS OF ζ URSÆ MAJORIS AND β AURIGÆ.—The periodic duplicity of the K line in the spectra of these stars before noted (January 23, p. 285) led Prof. Pickering to conclude that the time of revolution of the former system was 104 days. In the current number of the *Sidereal Messenger*, however, Prof. Pickering adds a note, dated January 11, 1890, in which he records that later observations make it probable that the period of ζ Ursæ Majoris is 52 days instead of 104, and that its orbit is noticeably elliptical. The velocity of the components of β Aurigæ seems to be 150 miles per second, their period 4 days, their orbit nearly circular, with a radius of 8,000,000 miles, and their masses 0·1 or 0·2, that of the sun being unity.

COMET BROOKS (*d* 1889).—The following ephemeris is given by Dr. Knopf in *Edinburgh Circular* No. 5, issued on the 22nd inst. :—

1890. March.	R.A. h. m. s.	Decl. ° ′	1890. March.	R.A. h. m. s.	Decl. ° ′
1 ...	2 22 54	+17 58·6	15 ...	2 49 26 ...	+20 8·0
3 ...	26 40	18 17·9	17 ...	53 17 ...	20 25·3
5 ...	30 26	18 36·9	19 ...	57 8 ...	20 42·3
7 ...	34 13	18 55·6	21 ...	3 0 59 ...	20 59·1
9 ...	38 1	19 14·1	23 ...	4 51 ...	21 15·6
11 ...	41 49	19 32·3	25 ...	8 43 ...	21 31·8
13 ...	45 37	19 50·3			

The brightness on March 1 = 0·24, and on March 25 = 0·17, that at discovery being unity.

NEW SHORT-PERIOD VARIABLE IN OPHIUCHUS.—Mr. Edwin F. Sawyer announces the discovery that the star 175 (*Uranometria Argentina*) Ophiuchi, R.A. 17h. 45m. 57s., Decl. − 6° 6′·7 (1875·0), is a variable of short period (*Astronomical Journal*, No. 210). The range of variation appears to be from 6·2m. to 6·95m., and the period slightly greater than 17 days.

OBSERVATIONS OF THE MAGNITUDE OF IAPETUS.—In the January number of *Monthly Notices* is found an interesting communication to the Royal Astronomical Society by Mr. Barnard, of the Lick Observatory, on the eclipse of this outermost satellite in the shadows of the globe, crape ring, and bright ring of Saturn. By frequent comparison of the light of Iapetus with that of Tethys and Enceladus, the effect of the shadow of the crape ring on the visibility of the satellite was tested, seventy-five comparisons being made. It was found that, after passing through the sunlight shining between the ball and the rings, Iapetus entered the shadow of the crape ring. As it passed deeper into this, there was a regular decrease in light until it disappeared in the shadow of the inner bright ring. From the observations it appears that the crape ring is truly transparent, the sunlight sifting through it. The particles composing it cut off an appreciable quantity of sunlight, and cluster more thickly, or the crape ring is denser, as it approaches the bright rings.

GEOGRAPHICAL NOTES.

AT the ordinary meeting of the Royal Geographical Society, on Monday, Mr. C. M. Woodford read a paper on "Further Explorations of the Solomon Islands." He has visited these islands three times, and in the present paper he described what he saw during his third visit, in 1888. He took up his residence in the small island of Gavotu, off the coast of Gola, or Florida Island, a place centrally situated for visiting Ysabel, Guadalcanar, and other islands. He stayed with a trader named Lars Nielson, who had since been killed and eaten by the natives, as had also three of his boys. Since last June no fewer than six white men had been murdered by the natives of the Solomon Group, out of a total white population estimated at about thirty. Mr. Woodford's principal object in his last journey was to identify the places visited by the Spanish Expedition under Mendaña that discovered these islands in the year 1568. In this, he thought he might say, he had been entirely successful. The Spaniards related that when they were between Florida and Guadalcanar they passed an island in the centre of which was a burning volcano. This island was now conclusively identified with the Island of Savo. The lecture was illustrated with photographs of natives of Guadalcanar and other places, as well as specimens of rude architecture, by means of the dissolving-view apparatus.

ACCORDING to the Copenhagen correspondent of the *Frankfurter Zeitung*, an Expedition for the exploration of Greenland will start next summer from Denmark. The plan of work has been arranged by the Naval Lieutenant Ryder. The party will consist of nine persons. They will have three boats, and a steamer will convey them to the eastern coast as soon as the condition of the ice will allow of a landing. It is proposed that the region lying between 66° and 73° north latitude shall be explored in the course of the summer, and that the party shall push as far as possible into the interior. Sledges will be employed during the winter. The Expedition will be provisioned and equipped for two years, at the end of which time the steamer will return to take them away, cruising along the east coast till they get down to the shore. The expenses have been estimated at from 250,000 to 290,000 kroner (equal to from about £13,900 to £16,100), and the project is so popular, and looked on so favourably by the Government, that it is practically certain that the Diet will grant the money.

THE Geographical Society of Vienna issues a circular letter, dated February 1890, announcing the election of officers made last December. The new President is Herr Hofrath Ritter von Hauer, Intendant des naturhistorischen Hofmuseums.

LOCUSTS IN INDIA.

IN 1889, parts of Sind, Guzerat, Rajputana, and the Punjab were much troubled by locusts. A report on these destructive creatures is being prepared under the direction of the trustees of the Indian Museum, Calcutta; and, in the hope that information about them, with specimens, may be obtained from persons who have had opportunities of observing them, Mr. E. C. Cotes, of the Indian Museum, has issued a preliminary note, summing up some of the principal facts that have already been brought together. This note is very interesting, and has been compiled chiefly from the records of the Revenue and Agricultural Department of the Indian Government.

The generally received idea is that the locust which invades India belongs to the species usually spoken of as *Acridium peregrinum*, and supposed to have been the locust of the Bible. The identity of Indian locusts has not yet, however, been definitely ascertained, and this is one of the points which require elucidation. As far as we at present know, there seems reason to believe that while *Acridium peregrinum* extends its ravages into the dry plains of the Punjab and Rajputana, the locust which proved injurious in Madras in 1878, and in the Deccan in 1882–83, belongs to a very different species, which is probably *Acridium succinctum*. In order to settle the question it will be necessary to examine further specimens taken from destructive flights which have appeared in various localities, the material in the Indian Museum being at present insufficient.

Dealing with the natural history of locusts generally, Mr. Cotes observes that all the different species which occur in various parts of the world breed permanently in barren elevated tracts where the vegetation is sparse. In years when they increase inordinately they descend in flights from their permanent breeding-grounds upon cultivated districts, where they destroy the crops, lay their eggs, and maintain themselves through one complete generation, but are unable to establish themselves permanently, usually disappearing in the year following the invasion, to be succeeded, after an interval of years, by fresh swarms from the permanent breeding-ground.

Generally speaking, the life circle of a locust extends through one year, in which period it passes through its various stages of egg, young wingless larva, active pupa, and winged locust, which dies after laying the eggs that are to produce the next generation. The eggs are laid in little agglutinated masses in holes, which the female bores with her ovipositor in the ground. In temperate climates the eggs are usually deposited in the autumn, but in sub-tropical countries, such as India, where there is but little winter, the winged locusts live on through the cold season, and only die off after depositing their eggs in the following spring. In this case the eggs hatch after lying in the ground for about a month. In both temperate and sub-tropical regions

alike, the young wingless locusts, on emerging from the eggs in the spring or summer, feed voraciously and grow rapidly for two or three months, during which period they moult at intervals, finally developing wings and becoming adult. The adult insects fly about in swarms, which settle from time to time and devour the crops. The damage done by locusts is thus occasioned in the first instance by the young wingless insects, and afterwards by the winged individuals into which the young are transformed after a couple of months of steady feeding.

In Rajputana and the Punjab in 1869 the flights were said to have come chiefly from the vast tract of sand hills (*Teeburs*) between the Runn of Kutch and Bhawulpore, and partly from the Suliman Range in Afghanistan. Locusts were reported as usually to be found in the autumn in the *Teeburs*, and it is thought that this tract is probably a permanent breeding-ground. The whole question, however, of the permanent breeding-grounds of these locusts is one that requires further investigation. The winged flights appeared throughout Central Rajputana in the latter part of the hot weather, and laid eggs which hatched as the rains set in; the old locusts dying after they had deposited their eggs. From these eggs were hatched young locusts which became full grown and acquired wings in August and September. The eggs laid by the original flights at the end of the hot weather were distributed throughout the whole of Central Rajputana, and a vast amount of injury was done, the crops being damaged, in the first instance, by the young locusts before they acquired wings, and afterwards by the winged swarms which flew about the country and settled at intervals to eat what had escaped the ravages of the young wingless locusts.

In the Punjab, flights of locusts, from the Suliman Range, Afghanistan, appeared in the western border, in the end of April and in May. Eggs and young locusts were also found about this time near the hills in the sandy tracts of the same district. The flights seem generally to have moved from west to east, and by July to have spread themselves throughout the Punjab; but the laying of eggs and the hatching out of young went on, at least in the south-east, throughout August and September.

In Bombay, locusts were noticed in May and June 1882, in the south-west of the Presidency; but they attracted little attention, such swarms being annual visitors of the Kanarese forests, and neither in Kanara nor in Dharwar did they cause any material injury. With the setting in of the south-west monsoon, however, they spread in flights over the Presidency to the north and north-east, and early in the rains proceeded to lay their eggs and die. These eggs hatched in the end of July and beginning of August, and the young locusts did a large amount of damage, over a wide area, through the months of August and September. In the early part of October, with the setting in of the north-east monsoon, the young locusts, which had by this time acquired wings, took flight, and travelled with the prevailing wind in a south-westerly direction, doing some injury in the Poona Collectorate as they passed. They then struck the Western Ghâts, and spread slowly over the Konkan in November, and thence travelled into the Native States of Sawantvadi and the Kanara district. During the remainder of the cold season and the following hot weather (December 1882, to the end of May 1883), the flights clung to the Ghâts, occasionally venturing inland into Belgaum, Dharwar, the Kolhapur State, and Satara, and devouring the spring crops in the Coast Districts, but ordinarily keeping in the vicinity of the hill ranges. With the commencement of the south-west monsoon, in the latter part of May 1883, the flights began to move in a north-easterly direction, as they had done the preceding year, but in larger numbers.

At the commencement of the rains they began to alight in vast numbers over an immense tract of country, comprising six Deccan Collectorates and three Coast Collectorates. They deposited their eggs and died; and early in August the young locusts hatched out in countless numbers, but were apparently more backward, and possessed of less strength and stamina than were those of the previous year. The unusually heavy rainfall killed vast numbers of them in some parts of the country, and elsewhere the insects seemed stunted and feeble, and grew but slowly. They were destroyed in vast numbers by the vigorous measures initiated by Government officers, and were also said to be diseased and attacked by worms and other parasites. As late as November, the mass of the young locusts appeared still unable to fly, and made no general move, as they had done the year before, towards their permanent home in the south-west. The invasion was in fact at an end, and though swarms appeared in Sawantwadi in 1883-84, no further injury of a serious nature seems to have occurred.

The injury occasioned to the rain crops by the locusts was very considerable, over a great portion of the Deccan and Konkan, both in 1882 and 1883. But it was found, at the end of the invasion, that abundance of the cold weather crops had compensated to so great an extent for the injury done to the rain crops, that, on the whole, no very widespread suffering had arisen.

In 1878, when the Madras Presidency was invaded, the young locusts began to appear in January, and were found in great numbers in different districts from then on till September and October, the earlier swarms being found in the west and south of the Presidency, and the later ones in the north and east. Winged locusts were first observed, in the end of March and beginning of April, in the hills to the south-west (Wynaad and Nilgiri), where they may be supposed to breed permanently. Thence, aided by the south-west monsoon, they gradually worked their way over the Presidency to the east and north, finally disappearing about November and December.

The information hitherto obtained hardly justifies any very decided conclusion as to the life history of the locust. But it may be noticed that locusts were observed pairing in the Salem District, in the latter part of June, and also that the young locusts, which were found, in the early part of May, in the Udamalpet *Taluk*, were supposed to be the offspring of the large flights of winged locusts which had appeared in the preceding February in the same *taluk*. The connection between the autumn broods of locusts and those which appeared in the early part of the year has not been made out satisfactorily.

Mr. Cotes ends his paper with an account of the chief measures which have at different times been adopted in India against locusts, pointing out that, the locust of North-West India being distinct from that of South-West India, measures found useful in one invasion are not necessarily applicable in another.

FIELD EXPERIMENTS ON WHEAT IN ITALY.[1]

PROF. GIGLIOLI, of the Agricultural College at Portici, a graduate of the Royal Agricultural College, Cirencester, has given to the Association of Proprietors and Farmers of Naples a voluminous and most carefully compiled Report on the results of the first year's experiments on wheat-growing at the experimental field of Suessola, about six kilometres fom Acerra. The field is on the estate of Count Francesco Spinelli, who generously lends it to the Association for experimental purposes. The district was celebrated in olden time for its fertility, but was afterwards long neglected on account of its marshy nature, and the land became sour and productive of disease. Now, again, drainage and improved cultivation have changed these marshes into some of the best land of a fertile district. The soil of the experimental field is easily worked, friable, and bears a good natural vegetation; no analysis of it, however, is furnished. Giglioli points out that it is in too high condition at present for comparative manuring experiments, but admirably suited for comparing different varieties of corn and different methods of sowing and cultivation, as by dibbling and the Lois-Weedon system.

There are in all 102 plots devoted to trying the effects of different manures, each plot being about 43 square metres; 18 unmanured plots of a similar size devoted to different varieties of wheat; and 3 plots, each about twice the above-mentioned size, used for different methods of seeding and cultivation. Paths were made round each plot, the paths being at rather a lower level than the plots themselves The author discusses the question of large and small plots, but concluded that under the conditions obtaining, small plots were the best for use here.

On the 102 manured plots, Scholey squarehead wheat was sown, with a great variety of manures—organic, nitrogenous, phosphatic, and potassic; but it was afterwards found this variety of wheat was, unfortunately, not well suited to the climate and to the general purpose of these experiments.

The 18 varieties experimented with, on the second series, included several well-known English varieties, such as Hallett's pedigree white and red wheats, Chiddam, golden drop, Hunter's

[1] "Resultati del Primo Anno di Esperimento sulle Varietà e sui Concimi del Frumento al Campo Sperimentale di Suessola nell' Anno Agrario 1887-88." By Italo Giglioli. Pp. 508. (Naples, 1889.)

white and Victoria white, also some Hungarian wheats, besides Italian varieties.

It was found that the English varieties gave very poor results; the squarehead was a very poor sample indeed, and it was unfortunate that it was used for the manuring experiments. The degeneration of English wheats during the first year is probably due to the great amount of transpiration taking place in this climate, especially during such a hot and dry summer as that of 1888. Giglioli enters into an interesting discussion of this important physiological result.

The most productive wheat was a variety known as Noé, from the South of France, originally from Bessarabia—this yielded at the rate of 3485 kilograms per hectare; next in order were two Italian varieties, Rieti and Puglia grain, yielding at the rate of about 3150 kilograms per hectare. The Puglia wheat was the finest in quality of grain, but its yield of straw was very low.

The great importance of a careful selection of varieties is pointed out, and Giglioli is of opinion that much more good will be done by improving and selecting Italian varieties than by importing new varieties; which, if from colder countries, will probably not be able to stand the climate.

Incidentally, the experiments showed the great benefit of good cultivation and of surface draining, the plots being above the level of the surrounding paths, for the produce of the unmanured plots was double that of the neighbouring land under ordinary cultivation.

From the manuring experiments it was shown that farmyard manure gave fair results, but the season was unfavourable to the action of artificial manures, being much too dry. Of nitrogenous manures, acidified urine gave the best results, but nitrate of soda and sulphate of ammonia were often worse than useless. Phosphates had some good effect, and Thomas-Gilchrist slag was useful. Potash salts had no particular effect; the chloride seemed rather better than the sulphate.

The results of the manuring experiments, considering the great care and labour bestowed on them, must be disappointing; but the soil is in too high condition for manures to show great effects, also the variety of grain sown was unsuitable to the climate, and the season was against manures, especially nitrogenous manures.

In this Report the details of the experiments are given in full, with the appearance of the plots at different dates, and the whole results tabulated in various ways in nearly a hundred tables. All the weighings at harvest were carried out under the personal superintendence of Prof. Giglioli, who evidently has spared neither time, trouble, nor health, in conducting these important researches. Already the results have yielded important information, especially on the suitability or the reverse of special varieties of wheat to the climate of Southern Italy, and with their continuance there can be no doubt that results most valuable to the Italian farmer on the cultivation and manuring of wheat will be obtained.

Whilst heartily congratulating Prof. Giglioli and the Agricultural Association of Naples on having inaugurated these experiments with the prospect of continuing them for some years, we cannot but think that their value would be greatly increased if the plots were larger; or, if this cannot be arranged with the appliances at command, if the experiments were always in duplicate, or preferably in triplicate, and this might be rendered possible by reducing the number of experiments on manures in future seasons.

E. K.

SCIENTIFIC SERIALS.

American Journal of Science, February.—The magnetic field in the Jefferson Physical Laboratory, by R. W. Willson. One of the wings of this Laboratory in Harvard University has been constructed wholly without iron for the purpose of research, and the author has made a series of experiments to determine how far the end sought has been gained. He has found the magnitude of the disturbance which may arise in practice from such objects as stoves and iron pipes, and has made the interesting discovery that the brick piers of the building have a sufficient amount of free magnetism to produce quite an appreciable effect.—On Cretaceous plants from Martha's Vineyard, by David White. The author has studied a number of fossil plants collected at several localities and horizons in the Vineyard series for the purpose of solving the question as to the age of the underlying clays, lignites, and sands, of Martha's Vineyard. He concludes that the evidence from the fossil plants bespeaks an age decidedly Cretaceous, and probably Middle Cretaceous, for the terrane in which they were deposited.—Review of Dr. R. W. Ell's second report on the geology of a portion of the Province of Quebec, with additional notes on the "Quebec group," by Charles D. Walcott. The geological systems recognized in the area reported upon include the Devonian, Silurian, Cambro-Silurian (Ordovician), Cambrian, and pre-Cambrian.—Measurement by light-waves, by Albert A. Michelson. The telescope and microscope are compared with the refractometer, some remarkable analogies in their fundamental properties are pointed out, and a few cases in which the last-named instrument appears to possess a very important advantage over the others illustrated. Previous experiments have shown that the utmost attainable limit of accuracy of a setting of the cross-hair of a microscope on a fine ruled line was about two-millionths of an inch, whereas direct measurements of the length of a wave of green light emitted by incandescent mercury vapour, show that the average error in a setting was only about one ten-millionth of an inch. The method is also extended to angular and spectrometer measurements.—On lansfordite, nesquehonite, a new mineral, and pseudomorphs of nesquehonite after lansfordite, by F. A. Genth and S. L. Penfield. The authors have examined the crystallization of lansfordite ($3MgCO_3.Mg(OH)_2 21H_2O$), and another new mineral having the composition $MgCO_3.3H_2O$, which has been named nesquehonite. A crystallized artificial salt of the same composition is also described.—Weber's law of thermal radiation, by William Ferrel. An examination of Weber's new law, and a test of his formula by means of experimental results, in which the absolute rate of losing heat is determined from the observed rate of cooling of heated bodies of known thermal capacity, and the relative rate from the galvanometer needle of the thermopile.—Tracks of organic origin in rocks of the Animikie Group, by A. R. C. Selwyn. Traces of fossils, or what are supposed to be such, have been discovered in the Animikie rocks of Lake Superior. The fact is interesting and important, for, if the black Animikie shales represent the Lower Cambrian of the Atlantic border, the Paradoxides and Olenellus fauna will probably be found in them sooner or later.

In the numbers of the *Journal of Botany* for January and February, two important monographs are commenced—by Mr. E. G. Baker, a synopsis of genera and species of Malveæ; and by Mr. G. Massee, a monograph of the genus *Podaxis*. This last genus of Fungi, Mr. Massee proposes to transfer, in consequence of the mode of formation of the spores, from the Gastromycetes, where it has hitherto been placed, to the Ascomycetes.

The *Botanical Gazette* for October 1889 contains an interesting summary of our present knowledge of protoplasm, by Prof. Goodale, in the form of an address to the Botanical Section of the meeting of the American Association for the Advancement of Science held at Toronto.

With the exception of an interesting paper by Prof. Massalongo, descriptive of some curious instances of teratology in the floral and foliar organs, the number of the *Nuovo Giornale Botanico Italiano* for January is chiefly occupied by a report of the proceedings of the Italian Botanical Society. Among a number of short papers, is one on the fertilization of *Dracunculus vulgaris*, the most important insect agent in which is stated by Prof. Arcangeli to be *Saprinus subnitidus*; one on the fertilization of *Arum pictum*, by Prof. Martelli; and one on the development of the picnids of Fungi, by Prof. Baccarini.

SOCIETIES AND ACADEMIES.

London.

Linnean Society, February 6.—Mr. Carruthers, F.R.S., President, in the chair.—Referring to an exhibition at a previous meeting, Prof. Stewart communicated some interesting observations on the habits of certain seaweed-covered crabs. He also made some remarks on the "pitchers" of *Nepenthes Mastersiana*, upon which criticism was offered by Mr. Thomas Christy, Prof. Howes, and Mr. J. Murray.—Prof. G. E. Boulger exhibited a series of original water-colour drawings of animals and plants of the Falkland Islands.—Mr. W. H. Beeby exhibited some forms new to Britain of plants from Shetland.—Mr. C. B. Clarke,

F.R.S., then read a paper on the stamens and setæ of *Scirpeæ*, illustrated by diagrams, which elicited a detailed criticism from Mr. J. G. Baker, to which Mr. Clarke replied.—A paper was then read by Mr. B. D. Jackson, which had been communicated by the late Mr. John Ball on the flora of Patagonia, prefaced by some feeling remarks by the President, on the loss which the Society had sustained through the recent death of this able botanist.

Zoological Society, February 18.—Dr. St. George Mivart, F.R.S., Vice-President, in the chair.—Mr. Tegetmeier exhibited and made remarks on two Cats' skulls, out of the large quantity of remains of these animals recently brought to this country from Egypt.—Mr. G. A. Boulenger read a report on the additions made to the Lizard collection in the British Museum since the publication of the last volume of the British Museum Catalogue of this group. A list was given of 91 species new or previously unrepresented in the collection. Ten species and three genera were described as new.—Mr. P. L. Sclater, F.R.S., read some notes on a Guinea-fowl from the Zambesi, allied to *Numida cristata*, and gave a general account of the recognized species of this group of Gallinaceous birds.—Dr. Mivart, F.R.S., read some notes on the genus *Cyon*, mainly based on an examination of the specimens of this genus of Canidæ contained in the British Museum.—Mr. P. L. Sclater, F.R.S., read a paper containing the characters of some new species of the family Formicariidæ.—Dr. Augustine Henry read some notes on the Mountain Antelopes of Central China (*Nemorhedus argyrochætes* and *N. henryanus*).

Royal Meteorological Society, February 19.—The following papers were read:—Observations on the motion of dust, as illustrative of the circulation of the atmosphere, and of the development of certain cloud forms, by the Hon. Ralph Abercromby. The author has made numerous observations on the motion of dust in various parts of the world, especially on deserts on the west coast of South America. He finds that the wind sometimes blows dust into streaks or lines, which are analogous to fibrous or hairy cirrus clouds; sometimes into transverse ridges and furrows, like solid waves, which are analogous to certain kinds of fleecy cirro-cumulus cloud; sometimes into crescent-shaped heaps with their convex side to the wind, which are perhaps analogous to a rare cloud form called "mackerel scales"; sometimes into whirlwinds, of at least two if not of three varieties, all of which present some analogies to atmospheric cyclones; sometimes into simple rising clouds, without any rotation, which are analogous to simple cumulus-topped squalls; and sometimes into forms intermediate between the whirlwind and simple rising cloud, some of which reproduce in a remarkable manner the combination of rounded, flat, and hairy clouds that are built up over certain types of squalls and showers. Excessive heating of the soil alone does not generate whirlwinds; they require a certain amount of wind from other causes to be moving at the time. The general conclusion is, that when the air is in more or less rapid motion from cyclonic or other causes, small eddies of various kinds form themselves, and that they develop the different sorts of gusts, showers, squalls, and whirlwinds.—Cloud nomenclature, by Captain D. Wilson-Barker. The author proposes a simple division of cloud-forms under two heads, viz. cumulus and stratus, and recommends that a more elaborate and complete division should be made of these two types. A number of photographs of clouds were exhibited on the screen in support of this proposal.—An optical feature of the lightning flash, by E. S. Bruce. It has been stated in the Report of the Thunderstorm Committee of the Royal Meteorological Society, that there is not the slightest evidence in the photographs of lightning flashes of the angular zigzag or forked forms commonly seen in pictures. The author, however, believes that this is an optical reality, as the clouds on which the projection of the flash is cast are often of the cumulus type, which afford an angular surface. In support of this theory he exhibited some lantern slides of lightning playing over clouds.

Anthropological Institute, February 11.—Dr. Garson, Vice-President, in the chair.—Mr. T. W. Shore read a paper on characteristic survivals of the Celts in Hampshire. He considered the round huts of the charcoal-burners a survival of the huts which were common in the Celtic period; and some of the industries of the Celtic period appear to have survived in Hampshire to the present day, such as that of osier-working or basket-making. There can be little doubt that Hayling, anciently spelt Halinge, has derived its name from the Celtic word *hal* = salt; the salt works which still exist there are in all probability an example of a survival of a Celtic industry. Several instances were given of earthworks which must be ascribed to the Celts, and it was suggested that the mounds upon which many ancient churches in Hampshire are built may have been sacred sites of the same people. Reference was made to the peculiar orientation of many Hampshire churches, 20° north of east, and it was explained as a survival of a reverence for the May Day sunrise from Celtic pagan time to Saxon Christian time, and under a modification to a later date.—Dr. Garson exhibited and described some skulls dredged from the bed of the Thames by Mr. G. F. Lawrence, who afterwards gave an account of the strata in which they were found.

Mathematical Society, February 13.—J. J. Walker, F.R.S., President, in the chair.—Mr. S. Roberts, F.R.S., read a paper concerning semi-invariants.—Mr. Tucker (Hon. Sec.) communicated papers by Prof. K. Pearson, on ether-squirts; by Prof. G. B. Mathews, on class-invariants; and a note on the imaginary roots of an equation, by Prof. Cayley, F.R.S.

PARIS.

Academy of Sciences, February 17.—M. Hermite in the chair.—Observations of minor planets made with the great meridian circle and Jardin's meridian circle at the Paris Observatory during the first three months of 1889, by Admiral Mouchez. Comparisons with published ephemerides have been made in the following cases: Victoria (12), Astræa (5), Parthenope (11), Hebe (6), and Eugenia (45).—On the movements of planets, supposing their attraction represented by one of the electro-dynamic laws of Gauss or Weber, by M. F. Tisserand. The author has investigated the motions of Mercury and Venus on the hypothesis that they were not governed by Newton's law of gravitation, but by one of the above named. The change of the longitude of perihelion for a given time would be about twice as great, using Gauss's law, than by using Weber's. Taking the velocity of light as 300,000 kilometres per second, it is found that, on the hypothesis of Weber's law, the major axis of Mercury's orbit would have a direct motion of 14"·4 in a century; for Venus the variation would be only 3"·0. Using Gauss's law, the value for Mercury becomes 28"·2.—Posthumous article on polyhedrons by Descartes; a note by M. de Jonquiemes, in which he shows that Descartes not only knew and employed the relation $S + F = A + 2$, but that he announced it explicitly, and prior to Euler.—On a new reviving plant, by M. Ed. Bureau. Two specimens of a supposed new plant which revived when placed in water, similar to the Rose of Jericho, have been investigated. The change, however, is not simply hydration, as in the latter plant. The specimens, which were found in Arkansas, prove to be the *Polypodium incanum*, Pluck, but the above property does not appear to have been previously observed in it.—On the distribution of pressures and velocities in the interior of liquid sheets issuing from weirs without lateral contraction, by M. Bazin.—On some objections to the theory of deep vertical circulation in the ocean, by M. J. Thoulet. It is concluded that the circulation of water between the equator and the Poles only affects a depth of about a thousand metres. Below this the water is in a state of repose. The conclusion has been arrived at from a consideration of deep-sea sediment and the observations of the density of water at great depths given in the *Challenger* Report.—On the St. Petersburg problem, by M. Seydler. Two solutions are given of this "probability" problem.—On the regular surfaces of which the linear element is reducible to the form of Liouville, by M. Demartres.—On the surfaces of which the linear element is reducible to the form $ds^2 = F(U + V)(du^2 + dv^2)$, by M. A. Petot.—Summary of the observations of the total solar eclipse of December 22, 1889, by M. A. de la Baume Pluvinel.—Note on the calculation of the compressibility of air up to 3000 atmospheres, by M. Ch. Antoine. In the expression $pv = D(\beta + t)$ (the pressure, p, being given in atmospheres, and the volume, v, in litres), for air

$$\beta = 273·6 - \sqrt{p}.$$

If up to 40 atmospheres $D = 2·835$,
and beyond 40 atmospheres $D = 2·835 + 0·0018(p - 40)$,

the table given for air at $t = 0°$ is found to agree well with the experimental results of Regnault and Amagat.—Extension of the theorems relative to the conservation of the flux of force and of magnetic induction, by M. Paul Janet.—Upon batteries with

molten electrolytes, and upon the E.M.F. at the surface of contact of a metal and a melted salt, by M. Lucien Poincaré. The author finds the E.M.F.'s in this case to be nearly the same as those found by M. Bouty (*Comptes rendus*, t. xc. p. 217) in the case of saturated solutions.—Electrolysis by igneous fusion of the oxide and fluoride of aluminium, by M. Adolphe Minet. The author presents the result of three years' work on the electrolysis of the fused oxide and fluoride of aluminium, in a table which gives the quantity of metal obtained as a function of the time and of the quantity of electricity used.—Note by MM. P. Hautefeuille and A. Perrey, on the silico-glucinates of soda. In a preceding note, the authors have described a number of silico-glucinates of potash, obtained by heating together mixtures of silica, glucina, and the alkali, with neutral vanadate of potash. They now have applied the same method of mineralization with mixtures containing soda, heating to about 800°. Five forms, of different composition, have been thus obtained. Substituting tungstate for vanadate of soda, two species of crystals have been obtained, corresponding in composition with two of those obtained with vanadate as mineralizing agent.—Upon the *rôle* of foreign bodies in iron and steel; the relation between their atomic volumes and the allotropic transformations of iron, by M. F. Osmond. Prof. W. C. Roberts-Austen, studying the effect of minute percentages of foreign elements upon the mechanical properties of gold, found a relation between the results obtained and the position in the periodic table of the introduced elements, and has predicted a similar phenomenon in the case of iron. Reviewing his former work in the light of this new idea, the author has found the prediction to be verified. Shortly, it may be said that foreign bodies of small atomic volume tend to cause iron to assume or remain in that of its molecular forms in which it has itself the smaller atomic volume, bodies of great atomic volume produce the opposite effect.—M. J. Ville, on dioxyphosphinic and oxyphosphinous acids. In two preceding notes (*Comptes rendus*, t. cvii. p. 659, t. cix. p. 71), and in the present communication, it is shown that by the reaction of aldehydes upon hypophosphorous acid, two new classes of acids have been obtained, with the general formulæ:—

$$(1)\ \mathrm{PO}\begin{cases}(\mathrm{R\ .\ CH\ .\ OH})\\(\mathrm{R\ .\ CH\ .\ OH});\\\mathrm{OH}\end{cases}\qquad(2)\ \mathrm{PO}\begin{cases}\mathrm{H}\\(\mathrm{R{-}CH\ .\ OH}).\\\mathrm{OH}\end{cases}$$

—Dibromo-carballylic acid, by M. E. Guinochet. This acid has been obtained by the reactions of 4 equivalents of bromine upon one equivalent of aconitic acid in a sealed tube, heated for thirty-six hours to 115°-120°.—Estimation of uric acid in urine by means of a hot solution of hypobromite of soda, by M. Bayrac. The principle of the method consists in separating the uric acid from the urea and creatinin present by alcohol, and the titration of the isolated acid with sodic hypobromite at 90°-100°. Results are said to be as exaet as those obtained by the best known methods, while the process takes much less time.—Researches upon the pathogenic microbes in the filtered waters of the Rhone, by MM. Lortet and Despeignes.—Upon the nutrition of the fungus of the *muguet*, by MM. Georges Linossier and Gabriel Roux. A complete study of the mineral, carbohydrate, and nitrogenous foods required and the substances produced by this fungus is given.—The perception of luminous radiations by the skin, as exemplified by the blind Proteus of the grottos of Carniola, by M. Raphael Dubois. By a number of experiments upon *Proteus anguinis*, the author demonstrates that the sensibility of its skin to light is about half of the sensibility of its rudimentary eyes, and further that this sensibility varies with the colour of the light employed, being greatest for yellow light.—The wax-organs and the secretion of wax in the bee, by M. G. Carlet. The author's researches lead him to conclude: (1) the wax is produced by the 4 last ventral arches of the abdomen; (2) it is secreted by an epithelial membrane and not by the cuticular layer of these arches, nor by the intra-abdominal glands; (3) this secretory membrane lies between the cuticular layer and the lining membrane of the antero-lateral part of the ventral arch; (4) the wax traverses the cuticular layer and accumulates on its outer surface.—Experimental plant cultivation in high altitudes, note by M. Gaston Bonnier. The modifications produced in Alpine plants by the climate have been studied and some general conclusions drawn, among which the most interesting is: "For the same extent of leaf surface, the assimilation is much more considerable in Alpine plants than in those of lower stations, on account of the greater thickness of the palisade tissue and the abundance of chlorophyll."

BERLIN.

Physiological Society, January 31.—Prof. du Bois-Reymond, President, in the chair.—Dr. Grabower spoke on root-area of the motor nerves of the laryngeal muscles.—Prof. Munk made a further communication on the subject of the cortical visual areas. His earlier researches on the extirpation of these areas had shown that the retina may be regarded as spatially projected on to the visual area in such a way that its external portion corresponds to the external part of the visual area of the *same* side, while the inner portion corresponds to the inner part of the area of the *opposite* side, and the middle portion to the middle part of the visual area of the opposite side. The upper half of the retina corresponds to the anterior part of the visual area, and the lower half to the posterior. More recently, Prof. Schäfer, of London, has found that, when the visual areas are stimulated electrically, movements result which are confined entirely to the eyes; when the anterior part of the area is stimulated, the eye is turned downwards and towards the opposite side; and when the posterior part is stimulated, the movement is similarly towards the opposite side, but now upwards. When, however, the central part of the area is stimulated, the result is merely a movement towards the opposite side. It was shown by the speaker, as the result of a large number of experiments on dogs which he had performed in conjunction with Dr. Obregici, that these movements are not dependent on the stimulation of any motor centres or upon any ordinary reflex movements, but that they are really movements which accompany visual sensations. They were shown by careful analysis to result in the directing of the eye towards that point in space into which the visual perception is referred whenever any definite point of the retina is stimulated by light, the point stimulated in this case being the corresponding part of the electrically stimulated visual area. Thus when the anterior part of the area is stimulated, the lower portion of the retina is stimulated, the resulting visual image is consequently referred out upwards, and the eyes accordingly also move upwards and towards the opposite side. Similarly for stimulations of other parts of the visual area. These experimental stimulations hence afford an evidence of the detailed spatial projection of the retina on to the visual areas, which is as certain and even more convincing than the evidence obtained from localized extirpations of the areas. They further permitted of a more certain delimitation of the visual areas than had been possible in the earlier experiments. It is impossible to enter here into the many interesting details of these experiments, or to give any account of the lengthy discussion which followed Prof. Munk's communication.

Physical Society, February 7.—Prof. Kundt, President, in the chair.—Dr. Budde spoke on the very rapid rotation of a solid body, possessed of three unequal moments of inertia, about a fixed point. He developed very fully the equations which hold good for this motion, and dealt, at the end of his communication, with the physical experiments which might be performed in order to test the equations.—Dr. Feussner spoke on the methods which are employed at the Government Physico-technical Institute for the measurement of electrical resistances. He exhibited and explained the several instruments used, pointing out that in their arrangement the greatest importance must be attached to the very accurate measurements of temperature. For this purpose the wires are wound upon metallic cylinders in order to provide for the rapid cooling of the wires as they are warmed by the passage of the current: these are then submerged in petroleum, whose temperature is recorded by a thermometer immersed in the liquid, which is itself kept constantly stirred. German-silver wires have shown themselves to be unsuited for the purposes of constructing the standard resistances, since their resistance increases regularly with lapse of time; neither could this increase be done away with by heating the wires until they were quite soft. This tendency was attributed to the occurrence of a gradual crystallization, which depended chiefly upon the zinc in the alloy. On this account an alloy of copper and nickel was employed, which is known commercially as "patent nickel," and examined as to its suitability. Wires made of this alloy possess a very low temperature-coefficient, and were found to be almost absolutely constant after being heated to 100° C. If they are kept for some time after they are made and wound, and are then heated, they may be used as standards for comparison. Several other alloys were also tried, as, for instance, various combinations of copper and manganese. The speaker described the experimental measurements made with these wires, and stated that up to 30 per cent. of manganese, above which amount

it was not possible to draw a wire in this alloy, they have yielded a negative coefficient of temperature. When the alloy contained only a small percentage of manganese, the coefficient was very small, so that such wires would be suitable for the construction of standard coils. In conclusion, he described how the resistances are measured in the Government Institute. The method employed is that of compensation, and measurement of potentials.—Dr. Jäger announced that Dr. de Coudres, in Leipzig, had succeeded in detecting a thermo-electric tension between compressed and uncompressed mercury. The compression was produced either hydraulically or by means of its own weight acting through a column of mercury. It was found possible to determine with certainty the direction of the thermo-electric current, and to measure its intensity for given pressures and temperatures. The investigation is not yet completed, but Dr. de Coudres hopes to be soon in a position to give a full account of his experiments.

In the report of the meeting of the Berlin Physical Society, January 27 (p. 383), *for* Dr. Lehmann *read* Dr. Leman.

STOCKHOLM.

Royal Academy of Sciences, February 12.—Contributions to the flora of the Hieracia of South-Eastern Sweden, by Herr H. Dahlstedt.—On the remains of a bread-fruit tree from the Cenoman strata of Greenland, by Prof. A. G. Nathorst.—Report on researches in practical pomology and horticulture during a tour in France and Germany, by Herr C. V. Hartman.—On the lichens of the island of Bornholm, by Dr. P. J. Hellbom.—Algæ aquæ dulcis exsiccatæ quas distribuerunt, V. Wittrock et O. Nordstedt, Parts 18-21, exhibited and demonstrated by Prof. Wittrock.—The results of a determination of the rotation of the sun, executed during the years 1887-89 in the Observatory of Lund, by Prof. Dunér.—On the influence of the duration of exposure for a photographic image of a star, by Dr. Charlier.—Experimental determination of the principal elements of a divergent lens, by Dr. C. Mebius.—Derivatives of sulphur urates, by Dr. Hector.—On the $\beta_1 = \alpha_1$ bromium naphthalin sulphon acid, and on the constitution of the acids which are formed by the agency of concentrated sulphuric acid on β-naphthylamin, by S. Forsling.—Experiments on the humidity of the atmosphere, by Dr. K. H. Sohlberg.—Anatomical studies on the floral axes of diclinous Phanerogams, by Herr A. Grevillius.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, FEBRUARY 27.

ROYAL SOCIETY, at 4.30.—The Croonian Lecture—The Relations between Host and Parasite in certain Epidemic Diseases of Plants: Prof. H. Marshall Ward, F.R.S.
SOCIETY OF ARTS, at 5.—The Northern Shan States and the Burma-China Railway: William Sherriff.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Theory of Armature Reaction in Dynamos and Motors: James Swinburne.—Some Points in Dynamo and Motor Design: W. B. Esson.
ROYAL INSTITUTION, at 3.—The Three Stages of Shakspeare's Art: Rev. Canon Ainger.

FRIDAY, FEBRUARY 28.

AMATEUR SCIENTIFIC SOCIETY, at 8.—Practical Coal-mining: H. S. Streatfeild.
ROYAL INSTITUTION, at 9.—Evolution in Music: Prof. C. Hubert H. Parry.

SATURDAY, MARCH 1.

ESSEX FIELD CLUB, at 7.—Micro-Fungi of Epping Forest; how to Collect, Preserve, and Study Them: Dr. M. C. Cooke.
ROYAL INSTITUTION, at 3.—Electricity and Magnetism: Right Hon. Lord Rayleigh, F.R.S.

SUNDAY, MARCH 2.

SUNDAY LECTURE SOCIETY, at 4.—Apollonius of Tyana; the Story of his Life and Miracles: G. Wotherspoon.

MONDAY, MARCH 3.

SOCIETY OF ARTS, at 8.—Stereotyping: Thomas Bolas.
ARISTOTELIAN SOCIETY, at 8.—The Psychological Development of the Conceptions of Causality and Substance: G. F. Stout.
VICTORIA INSTITUTE, at 8.—Chinese Chronology: Rev. James Legge.

ROYAL INSTITUTION, at 3.—Electricity and Magnetism: Right Hon. Lord Rayleigh, F.R.S.

CONTENTS. PAGE

THURSDAY, MARCH 6, 1890.

THE SCIENCE COLLECTIONS AT SOUTH KENSINGTON.

It is satisfactory to learn that the Government has taken the first step towards carrying out the recommendations of the recent Commission on the South Kensington Museum. The Report of the Commissioners was to the effect that the Science Museums contained valuable apparatus which ought to be exhibited; that the buildings in which it is displayed are inadequate; and that the area of the exhibition space ought immediately to be increased by 50 per cent. Between the Natural History Museum in Cromwell Road and the Imperial Institute Road lies the strip of ground on which the new buildings must be erected. It belonged to the Commissioners of the 1851 Exhibition, and they were willing to sell at a price somewhat less than the valuation of the Office of Works, or at ten shillings for every pound of their own estimate.

The question to be decided was, whether the country could afford £100,000 to purchase the land necessary to carry out the Report of one of the strongest Commissions which has ever investigated such a subject, or whether the great group of Museums for which South Kensington is famous was to be cut into two by rows of mansions.

The Government, which certainly did not err through undue haste, felt that a case had been made out, that further delay was useless, that the land ought to be secured before time and labour were spent in discussing the details of the buildings to be erected upon it, and therefore they brought in a supplementary estimate for the sum required.

Then followed a debate of the kind by which the *prestige* of ordinary members of the House of Commons has been reduced to its present level. One member "affirmed that there were empty rooms in South Kensington Museum which might well be used for the display of exhibits," though a body of Commissioners appointed to investigate the state of the collections had reported in a directly opposite sense. Another "could not understand why all these educational collections should be established close to one another at South Kensington." In other words, he could not see that if there is to be at South Kensington a great training school for teachers of science and art, it is desirable that the students should have ready access to the national science and art collections, and that the collections themselves should benefit from the advice of the Professors who are familiar with them. These objections were not, however, raised by men who knew the facts. Approval was expressed from both sides of the House by those who have the interests of education at heart. Sir Lyon Playfair, Sir Henry Roscoe, Mr. Mundella, and Mr. Chamberlain, all spoke in favour of the vote, and Mr. Mundella put clearly what those who are acquainted with the Museum know to be the truth, when he said "this question had been pressing for the last ten years, because for the whole of that period the most valuable national science collections, such as no other country in the world possessed, had been housed in the most disgraceful manner."

The vote was finally carried by 144 to 67, and it is to be hoped, now that the Government have entered upon the path of progress, they will pursue it with determination.

No one would urge precipitancy. Due care ought to be taken that money's value is obtained for money spent; but as the question of principle has been decided after ten years' debate, we have a right to demand that progress shall not be delayed by mere blind obstruction to every proposal which involves outlay, but that those in whose hands the fate of the science collections rests shall make up their minds as to what ought to be done, and shall forthwith do it.

THREE RECENT POPULAR WORKS UPON NATURAL HISTORY.

Glimpses of Animal Life. By W. Jones, F.S.A. (London Elliot Stock, 1889.)

Toilers in the Sea. By M. C. Cooke, M.A., LL.D. (London: S.P.C.K., 1889.)

Les Industries des Animaux. Par F. Houssay. (Paris: J. B. Baillière et Fils, 1890.)

Mr. Jones's book is a charming little volume of 229 pages, with one illustration forming a frontispiece. There are, in all, seven chapters; dealing, in succession, with "Playfulness of Animals," "Animal Training," "Musical Fishes" (title ill chosen), "Nest-Building and Walking Fishes," "Luminous Animals," "Birds' Nests in Curious Places," and "The Mole." The author has been at immense pains to sift the voluminous literature of his subject (a task which he admits has involved a "somewhat unprofitable course of romance reading"). We find, as might be expected, citations of the old old stories of our youth; the climbing perch, Cowper's hares, and other time-honoured (if perhaps too highly coloured) narratives appear; the luminous centipede is not overlooked; and authorities are appealed to, from Aristotle and the ancient classical writers of the past, down to Lubbock and Romanes ("the Rev. Dr. Romanes" [*sic*], p. 25) of to-day. The work is essentially a compilation; it consists mainly of a collection of lengthy extracts, and the author has left himself little room for originality. There results from this an occasional heaviness of style, which is especially noteworthy in the earlier portions of the volume. Paragraphs too frequently lead off with "Broderip mentions," "Evelyn records," "Humboldt saw," and the like; and not even stories of the gambols between a rhinoceros and an elephant, or of those of a 60-foot whale, serve to relieve the monotony. It is doubtful whether the author has not occasionally erred in the placing of his anecdotes. To take a leading instance; on p. 32 there is recorded the story of a parrot, "which, when a person said to it, 'Laugh, Poll; laugh!' laughed accordingly, and the instant after screamed out, 'What a fool to make me laugh!'" This narrative cannot be said to betray any sense of playfulness on the part of the bird, as would be inferred from its position in the text; it surely should have found a place under "Animal Training." The most serious defect in the book is the absence of an index. The author has brought together a very remarkable series of anecdotes; and if he would give us an

exhaustive index, together with a complete bibliography, his book would befit the more special and advanced student of animal life. Without these it can only appeal to the *dilettanti*; and we shall look for them in a future edition. We would point out, at the same time, that the climbing perch is referred to on p. 151 as *Perca*, and on 157 as *Anabas* (the latter being correct); that "Willmoes" (p. 185) should read Willemoes Suhm; and that Mr. Romanes does not lay claim to the distinction accorded him on p. 25 (*cf. supra*). The author, as he enters into details not usually met with in books of this kind, might advantageously incorporate with his account of the stickleback's nest, the discovery of Möbius and Prince that the thread employed in weaving it is secreted by the animal's kidney. So unique a fact in natural history should not be allowed to pass unnoticed; and that portion of the work which deals with the luminous fishes might well be brought more completely up to date.

Dr. Cooke's treatise is one of 369 pages, with 4 lithographic plates, 70 woodcuts, and an index. It deals with marine invertebrata, in their especial relations to skeleton formation; and the volume is especially designed to make good the shortcomings of the Rev. J. G. Wood's work, entitled "Homes without Hands." The book has its good points; the chapter on "Coral Reefs and Islands," and the "Introduction," are fairly well done. The last-named deals with generalities as affecting life and the conditions of life in the ocean depths; it gives a record of important explorations, from that of Ross in Baffin's Bay, to the *Challenger*; the Bathybius controversy is abstracted, and alternative theories of reef-formation are summarized, both being presented in concise and impartial language. On perusal, however, of the main portion of the book, we meet with a preponderance of antiquated, and often erroneous information. Lengthy citations from the writings of authorities of the last two or three decades are flaunted as if expressive of current knowledge and opinion. The question of sponge affinities is discussed as though settled by Clark and Kent; that of the significance of the yellow bodies of the Radiolarians as though set at rest by the misconceptions of Wallich. We are told that there is no proof that the Millepore is a Hydroid, and so on. Upon the ill-effects which must result from this method of procedure it is needless to enlarge; but in justice to the author it must be admitted that he has made some use of recent literature. He appeals to the *Challenger* volumes. His quotations from these are, however, very capricious, and in some instances inaccurate. It cannot be said that the spines of the Radiolaria are "never tubular," for Haeckel (whose Report the author quotes) has given their tubular character as a diagnosis of his *Phœodaria*. Writing of "sensation in the Radiolaria," the author indulges (p. 103) in a remarkable paragraph, which concludes as follows:—

> "Prof. Haeckel considers that the central capsule contains the common central vital principle, which he terms the 'cell-soul,' and that it may be regarded as a simple ganglion cell, comparable to the nervous centre of the higher animals, whilst the pseudopodia are analogous to a peripheral nervous system."

These are not the words of the author cited, and, even if they were, the introduction of such silly stuff into the pages of a book intended for "the large and increasing section of the nature-loving public who indulge in the use of the microscope as a source of instruction and amusement" (p. 3) is intolerable. It is a remarkable fact that, while the author has reproduced the more commonplace statements of the earlier writers in their original form, he should have chosen to give us the above, his own, rendering of the lucubrations of a Haeckel. In doing this he betrays a sad want of sound judgment. The public have a right to expect that a work of this type, intended to serve (p. 3) "as a preliminary to more specific knowledge, the direction of which they will thereafter be better able to choose," shall be up to date; but, to fulfil the useful purpose aimed at, such a work should rest upon a more authoritative foundation than the book now under review. That is amusing as an example of editorial piece-work among a somewhat antiquated literature, and to those familiar with the subjects approached it suggests reflections.

The volume by M. Houssay is one of 312 pages, with 47 woodcuts intercalated in the text (38 only are acknowledged on the title-page). The bulk of the work is divided into six chapters, dealing respectively with modes of capture of prey, of defence, of transport and storage of food, of provision for the young; of constructing or acquiring nests and habitations, and of preservation and protection of the same. The illustrations are, for the most part, admirable; some, which we take to be original, are fit to rank with the famous woodcuts in Brehm's "Thier-Leben," while others are already familiar to us from the pages of that work. In the introduction the author justly asserts that the naturalist of to-day lives more in the laboratory than in the field, that the scalpel and microtome have replaced the pins of the collector, and that the magnifier pales beside the microscope. This is, alas! too true. It cannot be denied that our present systems for the most part take insufficient heed of field-work, and we fully endorse the author's further remarks upon the changed aspect of affairs. The introduction as a whole deals with generalities in direct bearing upon those facts which follow; and by no means its least satisfactory feature is that it clearly sets forth what the author would have his readers understand by the title of his work. The main portion of the book is confined to bare records of observed fact, systematically arranged, and, where necessary, brought into special relationship by cross-references. That "talkee-talkee" so often forced into books of this kind is here withheld. Such comments as are indulged in are either confined to the introduction, or to a few concise paragraphs which make up the author's "conclusion"; and the latter is, as might be expected, devoted to a brief consideration of animal intelligence. In place of an index there is furnished a zoological table, in which the generic names of the animals written about are arranged in classificatory order, each being accompanied by a paged reference and a mention of that particular habit or industry dwelt upon. It is a pity that the author takes no cognizance of animals lower in the scale than the Arthropods; but we nevertheless heartily recommend his book to our readers. It is throughout popular, and written in that peculiarly pleasing, yet didactic, style, so characteristic of the works of the more successful of

French popularizers of science, which has made them masters of their art.

The above-named volumes are three of a number of similar treatises which have lately appeared. The appreciation of the beautiful and generally interesting in Nature must always precede the study of the more useful and special, and it is the highest function of works like the present to awaken this preparatory appreciation. Of such works those are the most valuable whose authors can claim a sound elementary knowledge of the facts with which they deal, and a familiarity with current research. Only on these terms can a popular natural history rise above the level of the too well-known type, in which the scissors supply the knowledge and the paste usurps the place of the co-ordinating intellect. G. B. H.

A GENERAL FORMULA FOR THE FLOW OF WATER.

A General Formula for the Uniform Flow of Water in Rivers and other Channels. By E. Ganguillet and W. R. Kutter. Translated from the German by Rudolph Hering and John C. Trautwine, Jun. (London: Macmillan and Co., 1889.)

THE general formula devised by Messrs. Ganguillet and Kutter for caculating the flow of water in both large and small channels, under varied conditions, was brought under the notice of English-speaking engineers by the publication, in 1876, of a translation by Mr. Jackson of some articles on the subject written by Mr. Kutter, which appeared in the *Journal der Cultur-Ingenieur* in 1870. This translation, however, was not authorized by Mr. Kutter, and contained some incomplete tables inserted by Mr. Kutter in his articles at the request of a friend. The present volume is a translation of the second edition of the treatise on the formula, written by Messrs. Ganguillet and Kutter, engineers in Berne, who have added a preface to the translation. Mr. Kutter died whilst this translation was in progress; and a short memoir of him, with a list of his works, is appended to the translators' preface.

The book commences with an historical sketch of the attempts to arrive at a formula for the flow of water in open channels; and the insufficiency of the earlier formulæ is pointed out. The investigations of Messrs. Darcy and Bazin, and the gaugings of the Mississippi by Messrs. Humphreys and Abbot, are then concisely described, and the formulæ which they deduced from the results of their experiments are given, the history of the subject, in a brief form, being thus brought down to the period at which Messrs. Ganguillet and Kutter commenced their investigations. This forms a sort of introduction to the account of the conception and development of the general formula, of which the various steps are described in detail. The modifications for various amounts of roughness are classified; and, finally, the formula is tested by the comparison of its results with a number of gaugings under very different conditions; and these results indicate, in considerably the greater number of cases, a closer approximation to the actual measurements than those obtained with the formulæ of either Humphreys and Abbot, or Bazin. A supplement gives a more direct derivation of the formula for mathematical readers; and the appendices contain numerous tables giving the flow of water in pipes under pressure, as well as in open channels, for practical use in English measures, derived from the formula, and also a diagram for the graphical determination of the values of the factors in the formula, adapted to English measures by the translators.

Most of the hydraulicians who had investigated the question before Darcy and Bazin, such as De Prony, Dubnat, Eytelwein, D'Aubuisson, Downing, and others, agreed in adopting a formula of the form $V = c\sqrt{RS}$, of which Brahms and Chezy are said to have been the authors in the latter half of the last century, in which V is the velocity, R the hydraulic radius, and S the slope. Different values were assigned to the factor c by the various investigators; but it was always regarded as a constant, applicable to any sized stream in most cases, to any slope, and to any state of the bed. Mr. Darcy was the first who directed attention to the influence the condition of the sides of channels and pipes exercised on the discharge; and he instituted a series of experiments, carried out after his death by Mr. Bazin, by which the flow of water in regular uniform channels, under different conditions of slope, form, and roughness of bed, was measured by careful gaugings and gauge-tubes. A few years previously, Messrs. Humphreys and Abbot had carried out their well-known gaugings of the flow of the Mississippi by means of double floats, and deduced a formula for the results obtained. Messrs. Ganguillet and Kutter found that the formula derived from the Mississippi experiments, relating to a large river with a very slight slope, was not applicable to the small streams with steep slopes of which they measured the flow in Switzerland, and also that Mr. Bazin's formula was not suitable, in its original form, for large rivers with irregular beds. This led Messrs. Ganguillet and Kutter to search for a formula applicable to very different slopes and sizes of channel, and adaptable to various conditions of bed. They took as the basis of their formula the various experimental results obtained in France and America, together with their own independent observations on channels with steep slopes, so as to include the extreme varieties of flow within the range of a single formula. Starting from Mr. Bazin's formula, $V = \sqrt{\dfrac{RS}{a + \dfrac{\beta}{R}}}$, where $c = \sqrt{\dfrac{1}{a + \dfrac{\beta}{R}}}$, they eventually found it expedient to express the value of c in the form $\dfrac{y}{1 + \dfrac{x}{\sqrt{R}}}$, in which, though they at first assumed y and x to be constant for any given state of bed, they finally modified them to expressions varying with the slope. The alterations in the formula were effected by aid of graphical representations of the various sets of gaugings. It was found, in investigating the various experimental results, that the factor c varied generally with the slope; but a somewhat anomalous result was also noted—namely, that whereas in the Mississippi observations c increased with a decrease in the slope, it on the contrary decreased with a decrease of slope in the gaugings of small channels, unless the wetted

perimeter was very rough. This change in the variation of c with relation to the slope was found to depend upon the hydraulic radius being greater or less than 3·281 feet; so that c becomes independent of the change in slope when R approximates to this value, though the actual value of R at which the modification occurs varies with the degree of roughness of the channel. This result is attributed to the conflicting currents and eddies in large rivers having irregular beds, or in small channels with very rough beds, which are intensified by an increase in the slope; whereas, in small streams flowing in confined channels with smooth beds, an increased velocity tends to dissipate retarding lateral movements. A preliminary form adopted for the value of c was $\dfrac{a+\frac{l}{n}}{1+\frac{an}{\sqrt{R}}}$, where $a+\frac{l}{n}$ replaces y in the original formula, and $an = x$, or $x = ny - l$, in which a is a constant with value 41·66 in English measures; l is another constant, equal to $\sqrt{R}$ when R has the special value 3·281 referred to above, and therefore 1·811; and n is the coefficient of roughness, varying, according to the state of the channel, from 0·009 to 0·040. The above value of c suffices for the flow in pipes and other small channels with steep slopes, owing to the small influence of a variation of slope on the coefficient c in such cases; but for ordinary channels allowance has to be made for variations in slope, necessitating the introduction of another variable factor into the expression for c. The final shape given to the value of c by Messrs. Ganguillet and Kutter, in their general formula, was $\dfrac{a+\frac{l}{n}+\frac{m}{S}}{1+\left(a+\frac{m}{S}\right)\frac{n}{\sqrt{R}}}$, where $m = 0·0028075$, for English measures, is a constant of a hyperbola employed in constructing the formula. The general formula, accordingly, became, for English measures—

$$V = \frac{\frac{1·811}{n} + 41·6 + \frac{0·00281}{S}}{1+\left(41·6+\frac{0·00281}{S}\right)\frac{n}{\sqrt{R}}}\sqrt{RS},$$

where V is the mean velocity in feet per second, which multiplied by the cross-section would give the discharge in cubic feet per second, and S is the actual slope.

The main interest of the book consists in the clear exposition of the several steps by which the formula was reached; and even if at some future time, by the aid of fresh observations and more accurate experiments, the formula should be superseded by a more comprehensive and exact one, the merit of this work as an elaborate scientific investigation for a general empirical formula must always remain; and the book would deserve to be consulted on this ground alone. The formula depends entirely upon the exactness of the observations upon which it has been based. Mr. Révy has questioned the accuracy of the Mississippi experiments, owing to the use of double floats; and if fresh investigations should establish the inaccuracy of any of the observations made use of, or if further experiments should extend the scope of the inquiry, or bring new facts to light, a modified formula will be required. The authors, however, of the formula do not regard it as final or complete, nor do they claim for it any mathematical precision; they only consider that it agrees more closely than any previous formula with the results of recorded observations. The formula has naturally been objected to on account of its complicated appearance; but the variation due to change of slope renders this inevitable; and it has been seen that a simpler formula may be adopted for pipes, and small channels with steep slopes; and, moreover, graphical methods and tables might simplify the calculations. At the close of last year, Mr. Robert Manning, Engineer to the Board of Works in Dublin, presented a new formula to the Institution of Civil Engineers of Ireland, which, in its general form, is hardly less complicated than that of Messrs. Ganguillet and Kutter. This formula is

$$V = n\sqrt{Sg}\left\{R^{\frac{1}{2}} + \frac{0·22}{m^{\frac{1}{2}}}(R - 0·15m)\right\},$$

where n is the coefficient of roughness, g the force of gravity, and m the height of the barometric column of mercury. Mr. Manning puts it forward as simpler and better than the other, and claims for it, in a simplified form, a closer approximation to the mean of the results of seven of the best known formulæ than any other. Actual observations, however, form a surer basis upon which to establish a general formula than the results of previous formulæ; and it is upon a close concordance with very varied and accurate observations that any general formula must claim acceptance. Whatever position may in the future be assigned to the formula of Messrs. Ganguillet and Kutter, their work marks a notable step in advance, and must rank with the researches of Messrs. Darcy and Bazin, and Messrs. Humphreys and Abbot, as a record of important hydraulic investigations; and the translators have performed a valuable service in placing clearly before English readers the successive steps by which this general formula has been established.

THE COMPASS ON BOARD.

Der Kompass an Bord: Ein Handbuch für Führer von eisernen Schiffen. Herausgegeben von der Direktion der Deutschen Seewarte. (Hamburg: L. Friederichsen and Co., 1889.)

THE important subject of the magnetism of iron ships and the resulting deviations of their compasses, has, during the last fifty years, received marked attention in England from eminent men of science, attended with most valuable results for the safe navigation of our Royal and mercantile navies.

During the last thirteen years this same subject has been one of continuous inquiry at the German Naval Observatory in Hamburg, and papers have been published from time to time in the annual report of that institution, showing what had been accomplished. Combining the results of this work with those obtained from the extensive literature chiefly produced in England, Dr. Neumayer, the Director of the Observatory, has compiled the present work for the use of officers commanding the iron ships of the German mercantile navy.

Of the six chapters into which the work is divided, the first is devoted to information on the magnetism of iron

and steel, terrestrial magnetism, and the means of obtaining the three magnetic elements.

In the second chapter, the various modern forms of the mariner's compass, and instruments for adjusting compasses without sights, are described with illustrations. There is much here which should be of value to commanders of ships anxious to know as much as possible of their best friend in navigation.

It is, however, to be regretted that in some particulars both text and illustrations belong to the past, for in Fig. 38 an imperfect idea is given of Sir W. Thomson's compass. The drawing was correct for 1877, but important improvements were made ten years ago in the substitution of the wire grummet suspension for india-rubber, a change attended with marked success in vessels propelled and severely shaken by powerful engines; also, in 1881, the adoption of a total reflection prism in the azimuth mirror instead of an ordinary piece of looking-glass.

Prominence is given to the Hechelmann compass card, which is intended to combine the principles of the Thomson card (which consist chiefly of a long period of oscillation and great lightness), with a much greater magnetic moment in the Thomson-Hechelmann card, as it may be termed. The chief difference in these cards lies in the arrangement of the needles, Hechelmann's idea being to suspend more powerful needles than Thomson's near the circumference, thus bringing the weight as far as possible from the centre of the card to produce a slow period.

In bringing powerful needles so near the circumference, it is easy to see that something has been lost by Hechelmann when the quadrantal deviation is to be corrected as it should be—a correction so perfectly accomplished by Thomson. The greater weight of the card, too, tends to increase friction at the cap and pivot. Under these considerations the Thomson-Hechelmann card can hardly be considered equal to the modern Thomson.

In the next chapter, which treats of the magnetism of ships and the resulting deviation, it is satisfactory to find that the different kinds of magnetism which careful investigation has shown to exist in modern vessels are specially mentioned. These are—

(1) Permanent magnetism.
(2) Sub-permanent (termed also retentive) magnetism.
(5) Transient magnetism.

These definitions are accompanied by a footnote stating that in the English text-books on deviation no difference is made between permanent and sub-permanent magnetism, but that the two are combined under the expression sub-permanent. This is perhaps rather hard upon some English books, where, by careful reading, it will be found that the distinction is really made, but, it must be confessed, with a want of that clearness of division which is important to sound knowledge. Readers of the papers published by the Royal Society, and more recently by the Royal United Service Institution, will find that the division of a ship's magnetism into the three kinds mentioned above is strongly insisted upon.

A complete analysis of the deviations of any given compass in a ship, and of the changes which take place on a change of latitude, is necessary before a satisfactory compensation of the deviation by magnets and soft iron can be made. In the "Compass on Board," this analysis has a chapter devoted to it, containing information which should be of value both to the captains of ships and compass adjusters. It is illustrated by many examples.

Values of the coefficients v and v', representing the temporary deviation caused by running on a given course for some days, are given for a number of vessels of different types, steam and sailing. They clearly show the navigator of a new ship the need of caution when altering course, and some idea of the amount of change of deviation he may expect; whilst it should be understood that no careful seaman would fail to learn and note the peculiarities of the iron affecting his ship's compasses from personal observation under the varied circumstances experienced during each voyage.

A corrector for the deviation caused by sub-permanent magnetism has yet to be discovered.

Taking a general view of this book, it may be described as calculated to provide good practical information for the officers of the German mercantile navy, as well as a certain amount of a theoretical nature for those inclined to learn something of a ship's magnetism from a higher standpoint.

The maps of the three magnetic elements provided at the end of the book are given for the epoch 1885, and on a larger scale than those usually provided in hand-books. The accompanying map of values of the secular change is somewhat open to criticism as regards the figures recorded in the Red Sea, Bombay, East Indies, and Australia. This, however, will not prove of any detriment to safety in practical navigation.

The difficulties connected with the compass in war-ships, with their armoured deck, thickly-plated sides, and conning-towers, are not treated of, and their officers must look elsewhere for the special information they require; still, there is much to be found in this book that will serve their purpose.

OUR BOOK SHELF.

Library Reference Atlas of the World. By John Bartholomew, F.R.G.S. (London: Macmillan and Co., 1890.)

THE recognition of the intimate connection that exists between physiography and geography is made very manifest, in all the atlases published during the last few years, by the insertion of maps indicating the physical features of the earth's surface.

We are in an eminently utilitarian age, and a collection of maps, to meet the requirements of the day, must serve more purposes than that of a mere index to the positions of places; it must represent the most permanent features of importance in commercial geography, and the distribution of commodities as explained by the sciences of physics, geology, meteorology, biology, &c., or collectively by physiography. The elegant work before us satisfies all these requirements, it is as complete as it is a trustworthy atlas of modern geography, and will be equally appreciated by the student, the business man, and the general reader.

The atlas contains 84 maps, and amongst them we find plates delineating drainage areas, ocean currents, prevailing winds, rainfall, temperature, climate, and commercial features. A characteristic of the collection is the large number of maps that have been devoted to the British Empire, eighteen plates being given of the United Kingdom alone. India is completed in eight plates, the Dominion of Canada is very completely represented in seven plates, and the mapping of all the British possessions

has been carried out on the same elaborate scale. After the British Empire, special prominence has been given to the United States, whilst all the other countries of the world have been treated in a very comprehensive manner. The general reference index comprises the names of 100,000 places contained in the maps, and for British names it is the most complete ever published. One matter of regret, however, is that the places on some of the maps are not obviously visible because of the bright and superabundant colouring used to indicate the divisions of a country, for, generally speaking, these divisions are better represented by coloured lines. The less masking there is, the more distinct must places appear, and therefore the purpose of an atlas will be the better served. This is, however, but a minor point. The atlas is an excellent one, it is complete and accurate, contains all the results of recent exploration and geographical research, and is issued at a moderate price; its addition to every library therefore is a thing to be desired.

The Bala Volcanic Series of Caernarvonshire and Associated Rocks; being the Sedgwick Prize Essay for 1888. By Alfred Harker, M.A., F.G.S., Fellow of St. John's College, and Demonstrator in Geology (Petrology) in the University of Cambridge. (Cambridge: University Press, 1889.)

IN this useful little work, Mr. Harker has given an admirable *résumé* of the results which have, up to the present time, been arrived at by the study of the ancient igneous rocks of North Wales. Besides summarizing the work of the late John Arthur Phillips and E. B. Tawney, of Prof. Bonney, Mr. Rutley, Mr. Cole, Mr. Teall, Mr. Waller, Miss Raisin, and others who have written on the petrography of the district, he has added many new and often judicious notes on the rocks in question. A number of fresh analyses, and the description of hitherto unrecognized varieties of rocks and minerals, raise the work out of the category of mere compilations; and the excellent classification and arrangement of his materials make the book one eminently useful for purposes of reference. It is unfortunate that it has no index, though the "table of contents," which is very full and carefully paged, causes the want to be less felt than it otherwise would be. Mr. Harker classifies the districts of Caernarvonshire in which volcanic rocks are found as the *Eastern*, *North-Western*, and *Western*, the latter consisting of the Lleyn peninsula. He groups the types of rocks represented under the headings of "rhyolitic lavas," "nodular rhyolites," "acid intrusives," "intermediate rocks," "diabase sills and basalts," and "other basic intrusions." The work concludes with a "review of vulcanicity in Caernarvonshire," in which we find discussions of the relation of the volcanic eruptions to the earth-movements that took place at the period of their occurrence, the succession of lavas in the district, and the evidence in favour of their submarine origin. The book is admirably printed, and is illustrated by six very clearly-drawn sketch-maps. The essay is worthy of the memorial in connection with which it appears, and is creditable to the University under whose auspices it is issued; and higher praise than this it would be difficult to give to any work of the kind.

LETTERS TO THE EDITOR.

The Inheritance of Acquired Characters.

WITHOUT expressing any opinion upon the question recently discussed in your columns under the above title, I think it may be as well to recall the belief of one whose judgment was not without weight, and to give some of the evidence on which that belief was founded.

In the first chapter of the "Origin of Species" (p. 8 of the sixth edition), Mr. Darwin says, respecting the inherited effects of habit, that "with animals the increased use or disuse of parts has had a more marked influence"; and he gives as instances the changed relative weights of the wing-bones and leg-bones of the wild duck and the domestic duck, and, again, the drooping ears of various domestic animals. Here are other passages taken from subsequent parts of the work:—

"I think there can be no doubt that use in our domestic animals has strengthened and enlarged certain parts, and disuse diminished them; and that such modifications are inherited" (p. 108). And on the following pages he gives five further examples of such effects. "Habit in producing constitutional peculiarities, and use in strengthening and disuse in weakening and diminishing organs, appear in many cases to have been potent in their effects" (p 131). "When discussing special cases, Mr. Mivart passes over the effects of the increased use and disuse of parts, which I have always maintained to be highly important, and have treated in my 'Variation under Domestication' at greater length than, as I believe, any other writer" (p. 176). "Disuse, on the other hand, will account for the less developed condition of the whole inferior half of the body, including the lateral fins" (p. 188). "I may give another instance of a structure which apparently owes its origin exclusively to use or habit" (p. 188). "It appears probable that disuse has been the main agent in rendering organs rudimentary" (pp. 400-401). "On the whole, we may conclude that habit, or use and disuse, have, in some cases, played a considerable part in the modification of the constitution and structure; but that the effects have often been largely combined with, and sometimes overmastered by, the natural selection of innate variations" (p. 114).

In his subsequent work, "The Variation of Animals and Plants under Domestication," he writes:—

"The want of exercise has apparently modified the proportional length of the limbs in comparison with the body" [in rabbits] (p 116). "We thus see that the most important and complicated organ [the brain] in the whole organization is subject to the law of decrease in size from disuse" (p. 129). He remarks that in birds of the oceanic islands "not persecuted by any enemies, the reduction of their wings has probably been caused by gradual disuse." After comparing one of these, the water-hen of Tristan D'Acunha, with the European water-hen, and showing that all the bones concerned in flight are smaller, he adds:—"Hence in the skeleton of this natural species nearly the same changes have occurred, only carried a little further, as with our domestic ducks, and in this latter case I presume no one will dispute that they have resulted from the lessened use of the wings and the increased use of the legs" (pp. 286-87). "As with other long-domesticated animals, the instincts of the silk-moth have suffered. The caterpillars, when placed on a mulberry tree, often commit the strange mistake of devouring the base of the leaf on which they are feeding, and consequently fall down; but they are capable, according to M. Robinet, of again crawling up the trunk. Even this capacity sometimes fails, for M. Martins placed some caterpillars on a tree, and those which fell were not able to remount and perished of hunger; they were even incapable of passing from leaf to leaf" (p. 304).

Here are some instances of like meaning from vol. ii.:—

"In many cases there is reason to believe that the lessened use of various organs has affected the corresponding parts in the offspring. But there is no good evidence that this ever follows in the course of a single generation. . . . Our domestic fowls, ducks, and geese have almost lost, not only in the individual but in the race, their power of flight; for we do not see a chicken, when frightened, take flight like a young pheasant. . . . With domestic pigeons, the length of sternum, the prominence of its crest, the length of the scapulæ and furcula, the length of the wings as measured from tip to tip of the radius, are all reduced relatively to the same parts in the wild pigeon." After detailing kindred diminutions in fowls and ducks, Mr. Darwin adds, "The decreased weight and size of the bones, in the foregoing cases, is probably the indirect result of the reaction of the weakened muscles on the bones" (pp. 297-98). "Nathusius has shown that, with the improved races of the pig, the shortened legs and snout, the form of the articular condyles of the occiput, and the position of the jaws with the upper canine teeth projecting in a most anomalous manner in front of the lower canines, may be attributed to these parts not having been fully exercised.

. . . These modifications of structure, which are all strictly inherited, characterize several improved breeds, so that they cannot have been derived from any single domestic or wild stock. With respect to cattle, Prof. Tanner has remarked that the lungs and liver in the improved breeds 'are found to be considerably reduced in size when compared with those possessed by animals having perfect liberty.' . . . The cause of the reduced lungs in highly-bred animals which take little exercise is obvious" (pp. 299–300). And on pp. 301, 302, and 303, he gives facts showing the effects of use and disuse in changing, among domestic animals, the characters of the ears, the lengths of the intestines, and, in various ways, the natures of the instincts.

Clearly the first thing to be done by those who deny the inheritance of acquired characters is to show that the evidence Mr. Darwin has furnished by these numerous instances is all worthless. HERBERT SPENCER.

LET me remind the readers of NATURE that the discussion which has been going on in these columns, between the Duke of Argyll and Mr. Thiselton Dyer, arose out of a reference in Mr. Wallace's book on "Darwinism" to the dislocation of the eyes of flat-fishes. Two views have been expressed as to the origin of this arrangement—the one endeavouring to explain it as a case in which a "sport" or congenital variation, had been selected and intensified; the other attributing it to the direct action of the muscles of ancestral flat-fishes which had pulled the eye out of its normal position, the dislocation thus established being transmitted to offspring, and its amount increased by like action in each succeeding generation. In common with Mr. Wallace and other naturalists, I spoke of this latter hypothesis as one of transmission of an "acquired character." The term "acquired character" was clearly enough defined by this example; it has been used in England for some years, and its equivalent in German (*erworbene Eigenschaften*) has been defined and used for the purpose of indicating the changes in a parent referred to by Lamarck in the following words ("Philosophie Zoologique," tome i. p. 235, édition Savy, 1873):—

"*Première Loi.*—Dans tout animal qui n'a point depassé le terme de ses developpements, l'emploi plus fréquent et soutenu d'un organe quelconque, fortifie peu à peu cet organe, le developpe, l'agrandit, et lui donne une puissance proportionnée à la durée de cet emploi; tandis que le défaut constant d'usage de tel organe, l'affaiblit insensiblement, le détériore, diminue progressivement ses facultés, et finit par le faire disparaître.

"*Deuxième Loi.*—Tout ce que la nature a fait *acquérir* ou perdre aux individus par l'influence des circonstances où leur race se trouve depuis longtemps exposée, et par conséquent par l'influence de l'emploi prédominant de tel organe, ou par celle d'un défaut constant d'usage de telle partie, elle le conserve par la génération aux nouveaux individus qui en proviennent, pourvu que les *changements acquis* soient communs aux deux sexes ou à ceux qui ont produit ces nouveaux individus."

The meaning of the term "acquired characters" is accordingly perfectly familiar to all those who have any qualification for discussing the subject at all. It is used by Lamarck, and has been used since as Lamarck used it. Naturalists are at present interested in the attempt to decide whether Lamarck was justified in his statement that acquired changes are transmitted from the parents so changed to their offspring. Many of us hold that he was not; since, however plausible his laws above quoted may appear, it has not been possible to bring forward a single case in which the acquisition of a character as described by Lamarck and its subsequent transmission to offspring have been conclusively observed. We consider that, until such cases can be produced, it is not legitimate to assume the truth of Lamarck's second law. We admit, of course, the operation of the environment and of use and disuse as productive of "acquired characters"; but we do not find any evidence that these particular characters so acquired are transmitted to offspring. Accordingly it has been held by several naturalists recently (whom I will call the anti-Lamarckians, and among whom I include myself) that it is necessary to eliminate from Mr. Darwin's teachings that small amount of doctrine which is based on the admission of the validity of Lamarck's second law. As everyone knows, Mr. Darwin's own theory of the natural selection of congenital variations in the struggle for existence is entirely distinct from Lamarck's theory, and the latter was only admitted by Darwin as being possibly or probably true in regard to some cases, and of minor importance. Although Darwin expressly states that he was more inclined to attach importance to Lamarck's theory in the later editions of the "Origin of Species," the anti-Lamarckians are convinced that it is conducive to the progress of knowledge to reject that theory altogether until (if ever) it is placed on a solid basis of observed fact; and in the meantime to try if it is possible to explain the cases which seem most favourable to Lamarck's view by the application of Darwin's own theory.

It is essential for those who are not thoroughly familiar with Darwin's writings to note that this does not involve a rejection of the conclusion that the action of external conditions upon a parent may be such as to modify the offspring. That is an important part of Mr. Darwin's own theory, and, as I recently pointed out in NATURE, it is to such action of the environment upon the parent that Mr. Darwin attributed the origin of those congenital variations upon which natural selection acts. This disturbance of the parental body (I compared it to the shaking up of a kaleidoscope), and with it of the germs which it carries, resulting in "sporting" or "variation" in the offspring, is, it should hardly be needful to state, a totally different thing to the definite acquirement of a structural character by a parent as the result of the action upon it of the environment, and the transmission to offspring of that particular acquired structural character. I am not concerned to inquire here whether, or how far, Prof. Weismann's theory of the continuity of the germ-plasm admits of the action of external forces on a parental body in such a way as to disturb the germ-plasm and induce variation. Prof. Weismann can very well defend his own views. All that I am concerned with—and that quite independently of the conclusions of Prof. Weismann—is whether it is or is not reasonable, useful, or indeed legitimate, to assume the truth of Lamarck's second law, in the absence of any direct proof that any such transmission as it postulates takes place. Those who think Lamarck's second law to be true have been urged to state (1) cases in which the transmission of acquired characters is directly demonstrated, or (2) cases in which it seems impossible to explain a given structure except on the assumption of the truth of that law. If they fail to do this, they are asked to admit that Lamarck's second law is unproven and unnecessary.

The response which has been made to this attempt to arrive at facts is beside the mark. Mr. Cope writes to NATURE merely *asserting*, "If whatever is acquired by one generation were not transmitted to the next, no progress in the evolution of a character could possibly occur,"—an opinion peculiar to himself, and certainly one which cannot be taken in place of fact. The Duke of Argyll then "interpolates" (to use his own word) a general statement of his beliefs, and in the last of his letters a statement of "what his position is." We really are not concerned in this matter with beliefs or positions. We want well-ascertained facts and straightforward reasoning from facts. The Duke of Argyll has not assisted us. When on a recent occasion he was asked to cite an instance of what he called "a prophetic germ" in the adult structure of a plant or animal having, in his opinion, such claims to this title as he had ascribed to the electric organ of skates, the Duke was unable to reply. He wrote as a substitute something about embryological phenomena, which had nothing to do with the case. He has not yet ventured to stake his oft-asserted right to offer an opinion upon zoological topics, on the reception which his attempt to deal with the details of a particular case of organic structure would obtain: in this, I think, he is wise.

The Duke similarly tries to evade the appeal to facts when he is pressed by Mr. Dyer to state cases of the transmission of acquired characters. In doing so, however, he has, it must be admitted, revealed an astonishing levity. He answers (par. 9 of his letter) that in all domesticated animals, and especially in dogs, we have constant proof that many acquired characters may become congenital. This is mere assertion; we require details. It is maintained, on the contrary, by anti-Lamarckians that the whole history of artificial selection, and of our domesticated animals, furnishes a mass of evidence against the theory of the transmission of acquired characters, since if such cases occurred they would be on record, and moreover would have been utilized by breeders.

The subsequent proceeding of the Duke is almost incredible. In the following paragraphs of his letter he gives up his contention that acquired characters are transmitted, coupling his retreat with unwarrantable charges against those who have lately raised the question as to whether this is the case or not. He correctly states what is meant by the term "acquired characters," and declares that this meaning has been expressly invented for the purposes of the present discussion by "for-

tuitists," and is "irrational." A more baseless charge was never yet made in controversy, nor a more obvious attempt to alter the terms of discussion so as to give some appearance of plausibility to a lost cause. The Duke, in fact, now at length tells us that *he* does not mean by "acquired characters" what *we* mean. Why then did he "interpolate" his remarks on the subject and make use of the term?

If the meaning which the phrase has for the scientific world generally be insisted upon, we are now, it appears, to understand that the Duke of Argyll agrees with us: what *we* mean by "acquired characters" are not, he admits, shown to be transmitted.

"Fortuitists," the Duke says, "have invented a new verbal definition of what they mean by 'acquired.'" I have shown at the commencement of this letter that the term "acquired" is used to-day as it was by Lamarck. To the Duke this meaning is "new"—because he has either never read or has forgotten his Lamarck. If this be so, the Duke has been writing very freely about a subject with which his acquaintance is very small. The alternatives are as clear as possible: either the Duke of Argyll knew the significance of the term "acquired characters" as employed by Lamarck, in which case it would have been impossible that he should charge those whom he calls "fortuitists" with having invented a new verbal definition of what they mean by "acquired"; *or* he did not know Lamarck's use of the phrase, and was therefore not qualified to offer an opinion in the discussion, nor to press his "beliefs" and "position" upon public attention.

I have no time and you have no space to devote to a full exposure of the character of other assertions made in the Duke of Argyll's "statement of his position" which are as reckless and demonstrably erroneous as that concerning the meaning of the term "acquired."

Perhaps the most flagrant of these is the assertion that "the theory of Darwin is essentially unphilosophical in so far as it ascribes the phenomena of variation to pure accident or fortuity" (paragraph 4). Of course the Duke cannot be acquainted with the following passage from the "Origin of Species," sixth edition, p. 106; but if he has to plead ignorance of the writings not only of Lamarck, but also of Darwin, what is the value of his opinions and beliefs on Lamarckism and Darwinism? The words of Mr. Darwin referred to are these:—"I have hitherto sometimes spoken as if the variations, so common and multiform with organic beings under domestication, and in a lesser degree with those under nature, were due to chance. This, of course, is a wholly incorrect expression, but it serves to acknowledge plainly our ignorance of the cause of each particular variation."

Whatever meaning the Duke may attach to the word "fortuity," it is mere empty abuse on his part to call the later Darwinians "fortuitists," and still less justifiable to insinuate that their investigations and conclusions are not guided by a simple desire to arrive at truth, but by the intention of propping up a worship of Fortuity. It is natural for the Duke to suppose it impossible to write on Darwinism without some kind of theological bias.

In conclusion, I venture to point out that the Duke of Argyll has (1) failed to cite facts in support of his assertions of belief in "prophetic germs," and "transmission of acquired characters" when challenged to do so; (2) that he displays ignorance of two of the most important passages in the works of Lamarck and of Darwin, whom he nevertheless criticizes, and in consequence of his ignorance completely, though unintentionally, misrepresents; and (3) that he has introduced into these columns a method of treating the opinions of scientific men, viz. by insinuation of motive and by rhetorical abuse, which, though possibly congenial to a politician, are highly objectionable in the arena of scientific discussion.

February 22. E. RAY LANKESTER.

Physical Properties of Water.

As you inform me that my anonymous critic (*ante*, p. 361) does not intend to avail himself of the opportunity I gave him (through you) of correcting his misstatements about my *Challenger* Report, I must ask to be permitted to correct them myself.

(1) There is nothing whatever in my Report to justify the critic's statement that I "*had never heard of* Van der Waals' work . . . till the end of the year 1888." Yet this is made the basis of an elaborate attack on me!

What I did say was to the effect that I was not aware, till Dr. Du Bois told me, that Van der Waals had given numerical estimates of the value of Laplace's K. I had long known, from the papers of Clerk-Maxwell and Clausius, the main features of Van der Waals' investigation. But I also knew that Maxwell had shown it to be theoretically unsound; and that Clausius had taken the liberty of treating its chief formula as a mere empirical expression, by modifying its terms so as to make it better fit Andrews' data. This paper of Clausius is apparently unknown to my critic, as is also my own attempt to establish (on defensible grounds) a formula somewhat similar to that of Van der Waals.

(2) I said nothing whatever about the "Volume of Matter in unit volume of Water." Hence the critic's statement, "Prof. Tait's value is 0·717," is simply without foundation.

I merely said that the empirical formula

$$p(v - \alpha) = \text{constant},$$

if assumed to hold for all pressures, shows that α is the volume when the pressure is infinite. I still believe that to be the case. If not, Algebra must have changed considerably since I learned it.

My critic speaks of a totally different thing (with which I was not concerned), which may be $\alpha/4$ or $\alpha/4\sqrt{2}$, or (as I think is more plausible) $\alpha/8$. But he says that liquids can be *compressed* to 0·2 or 0·3 of their bulk at ordinary temperatures and pressures. I was, and remain, under the impression that this could be done *only at absolute zero*, and then no compression is required

There are other misrepresentations of my statements, quite as grave as those cited. But it would be tedious to examine them all. I have no objection to a savage review, anonymous or not; on the essential condition, however, that it be *fair*. It is clear from what I have shown that this essential condition is absent.

But my critic, when his statements are accurate, finds fault with the form of my work. I will take two examples of this kind, and examine them.

(3) He blames me for not using C.G.S. units. The *Challenger* Reports are, as a rule, written in terms "understanded of" nautical men. I wonder what such men would have said of me, in their simple but emphatic vernacular, if I had spoken of a pressure of 154,432,200 C.G.S. units, when I meant what they call a "ton"; or, say, of 185,230 C.G.S. units, when I meant a "naut."

(4) I am next blamed for "mixing units."

I should think that if we could find a formula expressing, in terms of a man's age, the average rate at which he can run, say for instance

$$v = \frac{Ax(B - x)}{x^2 + C},$$

even my critic would express A in feet per *second*, and take x as the mere number denoting the age in *years*. Would he, alone in all the world, insist on expressing x as denoting the age in *seconds* in order to prevent what he calls the mixing of units? This is a case precisely parallel to the one in question.

Generally, I would remark that my critic seems to have written much more for the purpose of displaying his own knowledge than of telling the reader what my Report contains. For at least three of the most important things in my Report are not even alluded to:—the compressibility of mercury, the *nature* of Amagat's grand improvement of the *Manomètre Desgoffes*, and (most particularly) the discussion of the wonderful formula for the compressibility of water given in the splendid publications of the *Bureau International*.

P. G. TAIT.

THE last volume of the *Challenger* Reports contains papers on various branches of science. The review which appeared in NATURE was not the work of one writer, and was therefore not signed, but I have no desire to avoid taking full responsibility for the part of which I am the author.

It will be convenient to reply to Prof. Tait in paragraphs numbered to correspond with his own.

(1) Of course I fully accept Prof. Tait's account of his knowledge of Van der Waals' theory at the time when his *Challenger* Report was written, but I entirely dissent from his statement that what he said about it in the Addendum referred to in the review was "to the effect" described above.

It is hardly possible to do justice to my own case without quoting freely, but I will compress as much as possible. He

says (p. 60) that he "was informed" (which implies that he did not previously know) that "one of Van der Waals' papers . . . contains an elaborate study of the molecular pressure in fluids."

Again he says, "I have left the passages . . . which refer to this subject in the form in which they stood before I became acquainted with Van der Waals' work. I have not sufficiently studied his memoir to be able as yet to form a definite opinion whether the difficulty . . . which is raised in Appendix E. can, or cannot, be satisfactorily met by Van der Waals' methods."

Further, he states that he "had been under the impression . . . that Laplace's views had gone entirely out of fashion—having made, perhaps, their final appearance . . . about 1850."

As a matter of fact, Van der Waals adopted Laplace's views in 1873, and his formula differs from the expression $pv = RT$, only by the introduction of two terms, one of which is obviously an additional pressure such as is deduced from Laplace's theory.

I do not think that any reader could be expected to conclude from these passages in Prof. Tait's Addendum that when writing the paper he had long known the "main features of Van der Waals' investigation." To me they seemed to mean that he had not previously been acquainted with Van der Waals' work, nor with his methods, nor with the facts that he studied molecular pressure and adopted Laplace's ideas.

While, therefore, I willingly submit to Prof. Tait's correction of the phrase that he had "never heard of Van der Waals," I cannot admit that, on the evidence then before me, I did him any substantial injustice.

(2) I very much doubt whether the distinction between the ultimate volume and the molecular volume can be maintained if the equations are treated as empirical; and even if they are not, I doubt whether the ultimate volume, as defined by Prof. Tait, has any real physical meaning. The value of v when $p = \infty$ is independent of the temperature, whether deduced from the theoretical formula to which Prof. Tait refers (p. 48), or from those of Van der Waals or Clausius: hence it must (from this point of view) be the molecular volume. In the case of Prof. Tait's new equation, which was published after his Report was completed, and which is the only one I had not seen when I wrote the review, the results when we put $p = \infty$ or $T = 0$, are such as to show that its application to these extreme cases is not legitimate. My own view is that such algebraical solutions are worth very little, and I only discuss them because I wish to show that if we admit them at all they justify my treating Prof. Tait's number as an estimate of the molecular volume.

(3) I cannot say that I think that Prof. Tait's reason is adequate. The Royal Naval College at Greenwich has done more for our naval officers than he would have us believe, and, if it were not so, the *Challenger* Reports are not addressed to members of any one profession, nor intended for English-speaking scientific men alone. Their cosmopolitan character is shown by the fact that bound up in the same volume with Prof. Tait's Report is another by a distinguished Belgian geologist.

Foreigners have helped to describe the specimens which our Expedition collected; they will read the Reports which our experts have written. It would have required but a few minutes' work, and a few additional lines of print, to have given the final results in terms which they would have understood at a glance.

(4) The analogy is fallacious. Prof. Tait has devised a formula into which he introduces two quantities (age and speed), which are commonly expressed with reference to different units of time.

I pointed out that he had expressed in the same formula (contrary to common usage) the same quantity (pressure) in terms of two different units, of which one is not ordinarily used by many of those who will make use of his work.

As to the last paragraph, I have only two remarks to make, First, that I think Prof. Tait does himself injustice in regarding a description of apparatus devised by another, and the discovery of a blunder of the Bureau International, as two of the most important things in his Report. Secondly, that I think the imputation of motives should be banished from scientific discussions.

In conclusion, I wish to add that probably I should have left Prof. Tait's defence unanswered if he had not accused me of unfairness. I have no desire for any controversy, and no wish to impugn his knowledge of the theory of gases. But he will forgive my reminding him of the old saying, "*Noblesse oblige.*" A classical research should not be published in a state which leads the reader to the conclusion that the author was only just becoming acquainted with facts which bear upon his work and have been long before the world. As a reviewer, I formed the opinion that the Report under discussion was open to this criticism. As a reviewer, it was my duty to express my opinion in all honesty, and, as I hope, in all courtesy.

ARTHUR W. RÜCKER.

Visualized Images produced by Music.*

IN the annexed paper, and in her own words, are related the very curious effects produced on a lady friend by certain musical tones and orchestral combinations. They are so very singular, so entirely outside my experience, and, withal, so inexplicable, that I shall be glad if you will give them a place in your columns, in the hope that some of your readers—physiological or psychological—may be able to throw some light on them.

I should state that the lady is in perfect health, is very intelligent, an accomplished musician, and not at all, in this or any sense, the victim of a disordered imagination. She is quite conscious that these spectral images have only a subjective existence, though visually they have all the vividness of presentment which belongs to realities.

At the first blush it would seem as though these apparitions were in some way a response to stimuli sent through the auditory nerve; but this, if any, is an imperfect explanation, since it will be noticed that occasionally these visualized pictures *slightly precede the instrument they belong to.*

This fact suggests that a state of unconscious expectancy may be a factor in their reproduction, but it fails entirely, I think, to account for their initial appearance. GEO. E. NEWTON.

25 Woodland Road, Gipsy Hill, S.E.

"The sound of an oboe brings before me a white pyramid or obelisk, running into a sharp point; the point becoming more acute if the note is acute, blunter if it is grave. The obelisk appears to be sharply defined and solid if the note is loud, and vague and vaporous if it is faint. All the notes of the 'cello, the high notes of the bassoon, trumpet, and trombone, and the low notes of the clarionet and viola, make me see a flat undulating ribbon of strong white fibres.

"The tone of the horn brings before me a succession of white circles of regularly gradated sizes, overlapping one another. These circles and the ribbon float past me horizontally, but the point of the obelisk seems to come at me.

"In an orchestra, when the violins strike up, after the wind band has been prominent for a time, I see often, but not always, a shower of bright white dust or sand, very crisp and glittering. I am taking note of the recurrence of this impression, and think it is becoming more frequent, but it is not invariable like the others.

"I have heard a great deal of orchestral music all my life, but I have only noticed these effects for four or five years. They gained gradually in frequency and clearness, and now the first three are invariable.

"If I know the scoring of a piece well, the various effects *slightly precede* the instrument they belong to; only the objects are vague and faint till the sound begins.

"Sometimes, if an oboe passage has an intense and yearning character, the white point comes so near me, and moves so rapidly, that I think it *must wound me.*

"I am very anxious to make it clear that I am not trying to describe a mental state by symbols, but that *I actually see* the point, the fibres, and the circles. Generally they seem to float half-way between me and the orchestra.

"If only one class of instruments is used, the effect does not extend beyond the opening bars: for instance, in a string quartette I only see the white sand for a moment at the beginning; if, however, wind and stringed instruments are combined, I see the various effects again and again in one piece."

Foreign Substances attached to Crabs.

IN your issue of December 26, 1889 (p. 176), Mr. Pascoe drew attention to the cases of certain crabs which are frequently found covered with sponges, algæ, shells, &c., and brought forward also the well-known case of the Gastropod *Phorus*. He at the same time confessed that he could not see "where protection came in" in any of the cases which he cited. Mr. A. O. Walker, on the other hand (NATURE, January 30, p. 296), regards it as obvious that the attachment of these foreign substances is a useful adaptation for purposes of concealment. Prof. Herdman also (NATURE, February 13, p. 344) bears witness to the

'scarcely recognizable" appearance of the crab *Hyas* when covered with algæ, &c. Indeed, no one who has seen one of these crabs brought up with the dredge, or has found a well-covered *Stenorhynchus* on our own shores, can seriously doubt the usefulness of the habit in rendering the animal inconspicuous. In *Stenorhynchus* and *Inachus* the process of "dressing" with weeds and zoophytes has been described by Bateson (Journ. Mar. Biol. Association, vol. i. 1889, p. 213), and it is seen from his description that, as also in the cases of *Dorippe*, *Pagurus*, *Dromia vulgaris*, &c., the foreign substances or animals become attached to the body not by accident but by the act of the crabs themselves.

Now Mr. Walker, in regarding *all* these cases as instances of adaptation for concealment, has overlooked the fact that in two of our British species of hermit crab (*Pagurus bernhardus* and *P. prideauxii*) it is the habit of the animals to prefer, and often to fight for, shells which are rendered conspicuous by the attachment to them of species of Anemone, in the one case *Adamsia rondeletii* (*Sagartia parasitica*), in the other *Adamsia palliata*. Another British species (*Pagurus cuanensis*) is almost invariably found inhabiting a shell enveloped in the sponge *Suberites domuncula*, which is frequently of a conspicuous orange-red colour Only in the smallest species of *Pagurus* (*e.g.*, *P. lævis*) does the animal depend invariably upon an inconspicuous appearance for its safety.

The value to the crabs of a preference for shells to which Actinians are attached is found in the fact that these gaily-coloured animals are carefully shunned by fishes on account of their stinging powers; and although hermit crabs themselves are very palatable to fishes, their association with Actinians, while rendering them conspicuous as they move about, is at the same time an efficient protection from the persecution of their enemies.

This also explains the habits of the two Mauritian crabs, which, according to Möbius, carry about a sea-anemone in each claw.

The sponge with which *Pagurus cuanensis* is associated is (like all other sponges with which I have experimented) exceedingly obnoxious to fishes on account of its bad smell and taste. I have never succeeded in inducing a fish of any species to swallow a fragment of the sponge; but on the contrary the smell is in most cases quite sufficient to drive the fish away. The association with the sponge is therefore here also an efficient protection, for I know of no fish capable of extracting the crab from its retreat. It is seen from this that the case of *Dromia vulgaris* should probably be removed from the category of adaptations for concealment, and, like the cases of *P. bernhardus*, &c., be included in a special group of *warning* adaptations.

There yet remains the interesting case, adduced by Dr. R. von Lendenfeld, of *Dromia excavata* associated with a Compound Ascidian of the genus *Atopogaster* (Herdman). This, I believe, will be found to belong to the same category of warning adaptations, for after repeated experiments with Compound and other *Tunicata* at the Plymouth Laboratory I can state that these animals are essentially inedible to fishes. The inedibility is in large part due, as in the case of sponges, to the characteristic odour which *Tunicata*, and more especially Compound *Tunicata*, give out, and in no family (excepting perhaps the *Botryllidæ*) is this better marked than in the *Polyclinidæ*, the group to which *Atopogaster* belongs. Bearing in mind also the fact that Composite Ascidians frequently vie with sponges and Actinians in the possession of varied and conspicuous colours, it is rendered practically certain that the case of *Dromia excavata* is another instance of this same type of adventitious warning contrivances.

Thus the edible (the edibility is not yet proved for foreign species) *Crustacea* which attach foreign substances to their bodies may be divided into two groups:—

(*a*) Those which are rendered inconspicuous in relation to their natural surroundings by the habit; *e.g.*, *Stenorhynchus*, *Hyas*, *Dorippe*, *Pagurus lævis*, and young forms of *Pagurus bernhardus*, &c.

(*β*) Those which associate themselves with animals, easily recognizable by, and possessing qualities offensive to, their chief enemies; *e.g.*, *Dromia vulgaris* and *excavata*, *Pagurus bernhardus*, *prideauxii*, and *cuanensis*. WALTER GARSTANG.

Laboratory of the Marine Biological Association, Plymouth, February 21.

P.S.—From facts which Mr. Weldon and Mr. Harmer have communicated to me, it would appear that *Dromia vulgaris* frequently attaches Compound Ascidians (*Leptoclinum maculosum*, *Botrylloides Gasconiæ*) to its back instead of sponges, a variation of habit which is very interesting in connection with the apparently fixed habit of the Australian species.—W. G.

A Key to the Royal Society Catalogue.

"A CATALOGUER" appears to have misunderstood me in two points. In the index that I propose, the heads would not be numbered. Again, in forming an estimate of the size of the work, I made the supposition that the 8 papers of an author could be grouped, not under 8, but under 3 heads.

JAMES C. MCCONNEL.

A Meteor.

LAST night (Monday, the 3rd), as I was crossing the Old Deer Park to Richmond, I witnessed the flight of an exceptionally fine meteor, which shone out with great brilliancy notwithstanding the presence of a bright moon, which was almost at the full.

It appeared to start from the constellation of Leo, and travelled across the sky to the westward, vanishing some 10° or 15° above the horizon.

The night was very quiet at the time, and I heard no report.

T. W. BAKER.

Kew Observatory, Richmond, Surrey, March 4.

THE DISCOVERY OF COAL NEAR DOVER.

THE question of the existence of coal under the newer rocks of Southern England, which has engaged the attention of some of our leading geologists since the year 1855, has found its final answer in the discovery announced last week in the daily press. The story of the discovery is a striking example of the progress of a scientific idea, passing through various phases, and growing more clearly defined through opposition and failure, until ultimately it has been proved to be true, and likely to lead to industrial changes of national importance.

The question was originally started 35 years ago by Mr. Godwin-Austen in a memorable paper brought before the Geological Society of London, in which it was argued, from the character and arrangement of the coal-fields and associated rocks of Somersetshire and South Wales on the west, and of the Belgian and North French coal-fields on the east, that similar coal-fields lie buried beneath the newer strata of the intervening regions. Mr. Godwin-Austen pointed out that the general direction of the exposed coal-fields was ruled by a series of great east and west folds, running parallel to the great line of disturbance—"the axis of Artois,"—from the south of Ireland, through South Wales and Northern Somerset on the west, eastwards through Belgium and Northern France, into the valley of the Rhine, near Düsseldorf. Throughout this area the exposed coal-fields lie in long east and west troughs. This series of folded Carboniferous and older rocks formed also an east and west ridge along the line of the axis of Artois, which gradually sank beneath the waves of the Triassic, Liassic, Oolitic, and Cretaceous seas. Against this the strata of the three first of these rocks gradually thin off, while the coal-measures and other rocks of the ridge have repeatedly been struck in France and Belgium, and are now being worked immediately underneath the Cretaceous strata over a wide area.

The axis of Artois also, where it is concealed by the newer rocks in the south of England, is marked from Somerset eastwards by the anticlinal of the chalk of North Wiltshire, and the line of the North Downs, the general law seeming to be "that when any great folding and dislocation of the earth's crust has taken place, each subsequent disturbance follows the very same lines, and that simply because they are lines of least resistance."

Mr. Godwin-Austen, by combining all these observations, finally concluded that there were coal-fields beneath the Oolitic and Cretaceous rocks of the south of England,

and that they were sufficiently near the surface to allow of their being of great economic value. He further specified the line of the Thames Valley, and the region of the Weald, as possible places where they might be discovered.

These important conclusions were during the next 11 years generally received by geologists, with the exception of Sir Roderick Murchison. The next important step in the direction of their verification was that taken by the Coal Commission of 1866–67, by whom Mr. Godwin-Austen and Sir R. Murchison were examined at length, and the results of the inquiry embodied in the Report by Mr. Prestwich. In the Report, Mr. Godwin-Austen's views are accepted, and fortified by a vast number of details relating both to the coal-fields of Somersetshire and of France and Belgium. Mr. Prestwich also calls special attention to the physical identity of the coals of these two regions, and to the fact that the Carboniferous and older rocks in both are similarly disturbed. He concludes, further, that the coal-fields which now lie buried beneath the newer rocks are probably equal in value and in extent to those which are exposed in Somerset and South Wales on the west, and in Belgium and France on the east.

In 1872 the Coal Commission Report was published, and in the same year the Sub-Wealden Exploration Committee was organized[1] by Mr. Henry Willett to test the question of the existence of coal in the Wealden area by an experimental boring. The site chosen was Netherfield, near Battle, in Sussex, where the lowest rocks of the Wealden formation form the bottom of the valley. It was resolved to go down to the older Palæozoic strata, which were thought to occur at about 1000 feet from the surface, or to carry the bore-hole to 2000 feet if they were not struck before. The work was carried on under considerable difficulties for the next three years, until in 1875 it had to be abandoned at a depth of 1905 feet, because of the breakage of many hundred feet of lining-pipes, coupled with the loss of the boring-tool at the bottom. The section of the strata passed through is as follows:—

Netherfield Section.

		Feet.
Purbeck strata	... ...	200
Portland strata	... ...	57
Kimmeridge Clay[2]	...	1073
Corallian rocks[2]	... ...	515
Oxford Clay	... ...	60
		1905

This section, although it yielded no information as to the Palæozoic rocks, showed that in this particular district they are more than 1900 feet beneath the surface, and revealed the great thickness of the Kimmeridge Clay and Corallian rocks, sufficiently distant from the ridge of coal-measures and older rocks, against which the Oolitic strata thin away to the north, to allow of an accumulation of Oolitic sediments to a thickness of more than 1700 feet. In this respect, therefore, it afforded unmistakable evidence that the search for the ridge in question might be carried on with much greater chance of success further to the north, in the direction of the North Downs. The great and increasing thickness of the successive newer rocks of the Wealden formation, which form the surface of the ground between Netherfield and the North Downs, rendered it undesirable to repeat the experiment within the Wealden area proper. Close to Battle, the Secondary strata were of great thickness, and where the whole series of Wealden rocks were present, they were more than 1000 feet thick.

For the next eleven years the problem remained where it was left by the results of the Netherfield boring; while in the district of London, evidence was being collected in various sinkings for water, which proved the existence of the Palæozoic ridge of rocks, Silurian and old red sandstones, older than the Carboniferous, at about 1000 feet from the surface. Here, too, the Oolitic strata were not more than 87 feet in thickness, at their thickest point in the well at Richmond. The older rocks, moreover, were inclined at a very high angle, as in the case of the similar rocks underlying the coal-fields of Somerset, and of Northern France and Belgium, and this implied the existence of troughs of coal-measures in the synclinal folds, in neighbouring areas.

I come now to the last experiment, which has been so fortunately crowned with success. In 1886, I reported to Sir Edward Watkin that it was desirable, both on scientific and commercial grounds, for a boring to be put down in South-East Kent, in the neighbourhood of Dover, and that the Channel Tunnel works under the Shakespear Cliff would be the best site for the experiment. It was almost within sight of Calais, where the coal-measures had been proved at a depth of 1092 feet. It was also not many miles away from the spot where a large mass of bituminous material—which, according to Mr. Godwin-Austen, was the result of the distillation of coal from the measures beneath—had been discovered in the chalk. Sir Edward Watkin acted with his usual energy on my report, and the work was begun in 1886, and carried on, under my advice, down to the present time. The boring operations have been under the direction of Mr. F. Brady, the chief engineer of the South-Eastern Railway, to whose ability we owe the completion of the work to its present point, under circumstances of great difficulty. The strata passed through may be generalized as follows:—

Section at Shakespear Cliff, Dover.

		Feet.
Lower Grey Chalk, and Chalk-Marl	}	500.
Glauconitic Marl	}	
Gault	}	
Neocomian	}	
Portlandian	}	660.
Kimmeridgean	}	
Corallian	}	
Oxfordian	}	
Callovian	}	
Bathonian	}	
Coal-measures, sandstones, and shales and clays, with one seam of good blazing coal, struck at 1180 feet from the top of the bore-hole	}	20.

The coal-measures were struck at a depth of 1160 feet, or 68 feet below the point where the coal-measures were met with in the boring at Calais. It may also be noted as a remarkable confirmation of Mr. Godwin-Austen's views as to the abrupt thinning off of the Wealden strata, that, although along the line of the North Downs the Weald clay strikes towards the French coast, and is seen at low water between Hythe and Folkestone, it and the underlying Wealden strata are not represented in the section at the Shakespear Cliff.

It is too soon as yet to measure the full value of this discovery near Dover, while our work is as yet unfinished. We may, however, remark that the coal-fields of the Continent, which have been proved beneath the newer rocks in Northern France and Belgium, some 60 miles to the west of their eastern outcrops, have now been traced across the Channel, that they are at a workable depth, and that we have now a well-defined base for further researches in Southern England.

W. Boyd Dawkins.

[1] The Committee consisted of Profs. Ramsay and Phillips, Sir John Lubbock, Sir Philip Egerton, and Messrs. Thomas Hawksley, Warington Smyth, Prestwich, Bristow, Etheridge, Boyd Dawkins, and Topley.

[2] The precise boundary between these two groups is uncertain. If the Kimmeridge Clay series be taken down to the Coralline Oolite, its thickness will be 1512 feet.

THE RELATION BETWEEN THE ATOMIC VOLUMES OF ELEMENTS PRESENT IN IRON AND THEIR INFLUENCE ON ITS MOLECULAR STRUCTURE.

IN a lecture on the Hardening and Tempering of Steel, published in November last (NATURE, vol. xli. pp. 11, 32), an attempt was made to set forth the prominent facts developed in recent researches, more especially those of M. Osmond, which tend to prove that iron, like many other elements, can pass from the normal state to an allotropic one. It was shown that as a mass of iron or steel cools down, there are at least two distinct evolutions of heat, one occurring at a variable temperature not higher than 855° C., the other at a more constant temperature, near 650° C. From a long series of most patient investigations, Osmond argues that there are two kinds of iron, one [hard] β iron, and the other [soft] α iron. The molecular change from β to α iron is indicated by the first evolution of heat in the cooling mass of iron or steel, and at this point the cooling mass of iron regains the magnetic properties which it loses at higher temperatures. The second evolution of heat only occurs in carburized iron or steel, and marks the point at which carbon itself changes from the dissolved or 'hardening-carbon,' to the state of combined or 'carbide-carbon.' In highly carburized steel, the two points at which heat is evolved coincide, and experimental evidence has been given (*loc. cit.* p. 34) as to the abnormal molecular weakness which is exhibited when a very hot bar of such steel cools down to about 660° C. In a recent communication to NATURE (February 20, p. 369), Prof. Carl Barus, of Washington, has pointed out, with reference to this molecular weakness, "that when iron passes through the temperature of recalescence its molecular condition is almost chaotic"; whilst with regard to Osmond's view that α iron passes to β iron when submitted to any stress which produces permanent deformation of the mass, Prof. Barus says that "there is reason to be urged even in favour of the extreme view" that such molecular change may be produced in most metals. In the lecture at Newcastle, I expressed the belief (NATURE, *loc. cit.*) that it would be shown that the influence of small quantities of other elements on masses of iron would be found not to be at variance with the periodic law. I had already given experimental evidence to show that the action of small quantities of impurity on the tenacity of gold was closely in accordance with that law, but in the case of iron it was difficult to say what property of the metal would be most affected by the added matter. It appeared safe, however, to point to the possibility that the direct connection with the periodic law would "be traced by the effect of a given element in retarding or promoting the passage of ordinary iron to the allotropic state," a point of much importance, as the mechanical properties of the metal must depend on the atomic arrangement in the molecules.

I am glad that so eminent an authority and admirable experimenter as M. Osmond has satisfied himself as to the probable accuracy of this view. In two recent papers communicated to the Académie des Sciences, the results of his experiments are given, and the following is a translation of the later of these (*Comptes rendus*, vol. cx. p. 346):—

"Within the last few years and quite recently (*Comptes rendus*, Séances des 26 octobre et 6 décembre 1886, 4 avril 1887, et 3 février 1890), I have had the honour to submit to the Academy facts relating to the allotropic modifications of iron, and to the part played in such changes by foreign bodies alloyed with the mass. Prof. Roberts-Austen, by studying the effect produced on the mechanical properties of gold by the addition of the same weight (about 0·2 per cent.) of seventeen foreign metals, has discovered a curious relation between the results obtained and the position occupied by the added metals in the periodic classification (Phil. Trans. Roy. Soc., vol. clxxix. p. 339, 1888). Prof Roberts-Austen has deduced from this that an analogous relation should exist for iron, but the irons and steels of commerce are such complex products, and the same metal may assume such different aspects, that the relation in question is not readily apparent from a study of their mechanical properties.

"In reviewing my former experiments with these new ideas as guides, it appeared to me that the law of Roberts-Austen was well based, and new experiments undertaken to verify it have only confirmed my first view.

"The foreign elements whose action on the critical points of iron I have studied experimentally with more or less completeness, are ranged as follows in two columns in the order of their atomic volumes :-

I.	Atomic volume.	II.	Atomic volume.
Carbon	3·6	Chromium ...	7·7
Boron	4·1	Tungsten	9·6
Nickel	6·7	Silicon	11·2
Manganese ...	6·9	Arsenic	13·2
Copper	7·1	Phosphorus ...	13·5
		Sulphur	15·7

"The elements in column I., whose atomic volumes are smaller than that of iron (7·2), delay during cooling, *cæteris paribus*, the change of β [hard] iron to α [soft] iron, as well as that of 'hardening-carbon' (*carbone de trempe*) into 'carbide-carbon' (*carbone de recuit*). For these two reasons they tend to increase, with equal rates of cooling, the proportion of β iron that is present in the cooled iron or steel, and consequently the hardness of the metal. Indeed, their presence is equivalent to a more or less energetic hardening.[1]

"On the other hand, the elements of column II., whose atomic volumes are greater than that of iron, tend to raise or at least to maintain near its normal position, during cooling, the temperature at which the change of β to α iron takes place; further, they render the inverse change during heating more or less incomplete, and usually hasten the change of 'hardening-carbon' to 'carbide-carbon.'[2]

"Thus they maintain the iron in the α [soft] state at high temperatures, and must therefore have the same effect in the cooled metal. In this way they would act on iron as annealing does, rendering it soft and malleable, did not their individual properties, or those of their compounds, often intervene and partially mask this natural consequence of their presence.

"The essential part, therefore, played by foreign elements alloyed with iron, is either to hasten or delay the passage of iron, during cooling, to an allotropic state, and to render the change more or less incomplete in one sense or the other, according to whether the atomic volume of the added impurity is greater or less than that of iron. In other words, foreign elements of low atomic volume tend to make iron itself assume or retain the particular molecular form that possesses the lowest atomic volume, whilst elements with large atomic volume produce the inverse effect.

"It should be noted that carbon, whilst obeying the general law, possesses on its own account the property of undergoing, at a certain critical temperature, a change the nature of which is still disputable, although its existence is acknowledged. It is this property which gives carbon a place by itself in the metallurgy of iron."

M. Osmond has shown me the curves which represent the results of his experiments, and these will doubtless

[1] To the elements of column I. hydrogen may be added. As is well known, this element renders electro-deposited iron hard and brittle; perhaps it would be better to say with Graham *hydrogenium*, for hydrogen gas does not appear to have a marked influence on the critical temperature.

[2] Tungsten alone presents certain anomalies.

soon be published. Whatever may ultimately prove to be the true nature of the molecular change which accompanies the thermal treatment of iron and determines its mechanical properties, there is little doubt but that there is a close relation between the action of foreign elements and their atomic volume. Few metallurgial questions are of greater interest at the present time than those which relate to the molecular structure of metals, and the admirable work of M. Osmond has shown it to be very probable that the presence of a small quantity of a foreign metal may cause a mass of another metal to pass into an allotropic state. In relation to iron and steel the problems are of great industrial importance, and it is fortunate that we appear to be nearing the discovery of a law in accordance with which all metallic masses are influenced by "traces." W. C. ROBERTS-AUSTEN.

SEDGWICK AND MURCHISON: CAMBRIAN AND SILURIAN.[1]

ERRONEOUS impressions have long existed among American geologists with regard to the relations to one another, and to Cambrian and Silurian geology, of Sedgwick and Murchison. The Taconic controversy in this country served, most unreasonably, to intensify feelings respecting these British fellow-workers in geology, and draw out harsh judgments. Now that right views on the American question have been reached, it is desirable that the facts connected with the British question should be understood and justly appreciated.

Sedgwick and Murchison were literally fellow-workers in their earlier investigations. Prof. John Phillips, in a biographical sketch of Sedgwick (NATURE, vol. vii. p. 257), whose intimate friendship through fifty years "he had the happiness of enjoying," speaks thus, in 1873, of their joint work:—

"Communications on Arran and the north of Scotland, including Caithness (1828) and the Moray Firth; others on Gosau and the Eastern Alps (1829-31); and still later, in 1837, a great memoir on the Palæozoic strata of Devonshire and Cornwall, and another on the coeval rocks of Belgium and North Germany, show the labours of these intimate friends in the happiest way—the broad generalizations in which the Cambridge professor delighted, well supported by the indefatigable industry of his zealous companion."

Prof. Phillips then speaks of the Cambrian and Silurian labours "of two of the most truly attached and mutually helpful cultivators of geological science in England."

Of these Cambrian and Silurian labours it is my purpose to give here a brief history derived from the papers they published. They were begun in 1831, without concert—Sedgwick in Wales, Murchison along the Welsh and English borders.

In September of 1831, the summer's excursions ended, Murchison made his first report at the first meeting of the British Association. It was illustrated by a coloured geological map representing the distribution of the "Transition Rocks," the outlying Old Red Sandstone, and the Carboniferous limestone (Murchison, Report of the British Association, i. 91, 1831).

These "Transition Rocks" (of Werner's system), upturned semi-crystalline schists, slates, and other rocks, passing down into uncrystalline, and regarded as mostly non-fossiliferous, the "*agnotozoic*" of the first quarter of the century, were the subject of Sedgwick's and Murchison's investigations—the older of the series, as it turned out, being included in Sedgwick's part.[2] They were early resolved into their constituent formations by Murchison, and later as completely by Sedgwick in his more difficult field.[1]

Already in March and April of 1833, Murchison showed, by his communications to the Geological Society of London, that he had made great progress; for the report says:[2]—He "separated into distinct formations, by the evidence of fossils and the order of superposition, the upper portion of those vast sedimentary accumulations which had hitherto been known only under the common terms of Transition Rocks and Grauwacke." And these "distinct formations" were: (1) the Upper Ludlow rocks; (2) the Wenlock limestone; (3) the Lower Ludlow rocks; (4) Shelley sandstones, "which in Shropshire occupy separate ridges on the south-eastern flanks of the Wrekin and the Caer Caradoc"; (5) the Black Trilobite flagstone whose "prevailing Trilobite is the large *Asaphus Buchii*, which with the associated species," he observed, "is never seen in any of the overlying groups"; and below these, (6) Red Conglomerate sandstone and slaty schist several thousand feet in thickness.

By the following January, 1834, Murchison was ready with a further report,[3] in which he described the "four fossiliferous formations" in detail, and displayed, on a folded table arranged in columns, their stratigraphical order, thickness, subdivisions, localities, and "characteristic organic remains." The subdivisions of the rock-series in the memoir are as follows, commencing above: (I.) Ludlow rocks, 2000 feet; (II.) Wenlock and Dudley rocks, 1800 feet; (III.) Horderley and May Hill rocks (afterward named Caradoc), 2500 feet; (IV.) Builth and Llandeilo flags, characterized by *Asaphus Buchii*, 1200 feet; and, below these, (V.) the Longmynd and Gwastaden rocks, many thousand feet thick, set down as unfossiliferous.

Thus far had Murchison advanced in the development of the Silurian system by the end of his third year. Upper and Lower Silurian strata were comprised in it, but these subdivisions were not yet announced.

During the interval from 1831 to 1834, Sedgwick presented to the British Association in 1832 a verbal communication on the geology of Caernarvonshire, and another brief report of progress in 1833. A few lines for each are all that was published. The difficulties of the region were a reason for slow and cautious work.

In 1834, as first stated in the Journal of the Geological Society for the year 1852, the two geologists took an excursion together over their respective fields. Sedgwick says (Quarterly Journal of the Geological Society, viii. 152, 1852): "I then studied for the first time the Silurian types under the guidance of my fellow-labourer and friend; and I was so struck by the clearness of the natural sections and the perfection of his workmanship, that I received, I might say, with implicit faith everything which he then taught me." And further, "the whole 'Silurian system' was by its author placed *above* the great undulating slate-rocks of South Wales." The geologists next went together over Sedgwick's region, and

Printed from advance sheets kindly supplied by Prof. Dana. The article appears in the current number of the *American Journal of Science*.

Murchison says, in the introductory chapter of his "Silurian System," p. 4, "No one [in Great Britain, before his investigations began] was aware of the existence below the Old Red Sandstone of a regular series of deposits containing peculiar organic remains." "From the days of De Saussure and Werner, to our own, the belief was impressed on the minds of geologists that the great dislocations to which these ancient rocks had been subjected had entirely dissevered them from the fossiliferous strata with which we were acquainted."

[2] The term ... to the rocks of the Taconic region and their ... upturned, apparently unfossiliferous, semi-crys... extended eastward to a region of gneisses. The study of the rocks was commenced; but in 1842, before careful work for the resolution of them had been done—like that in which Murchison and Sedgwick were engaged—they were, unfortunately, put, as a whole, into a "Taconic system" of assumed pre-Potsdam age; at the same time "Transition" was shoved west of the Hudson, over rocks that were horizontal, and already resolved. Owing to this forestalling of investigation, and partly also to inherent difficulties, the right determination of the several formations comprised in this Taconic or "Transition" region was very long delayed.

[3] Murchison, Proc. Geol. Soc., ii. 13, 1834. The subject was also before the British Association; Report for 1834, p. 652.

the sections from the top of the Berwyns to Bala. Murchison concluded, after his brief examination, and told Sedgwick, that the Bala group could not be brought within the limits of his system. He says: "I believed it it to plunge under the true Llandeilo flags with *Asaphus Buchii*, which I had recognized on the east flank of that chain." "Not seeing, on that hurried visit, any of the characteristic Llandeilo Trilobites in the Bala limestone, I did not then identify that rock with the Llandeilo flags, as has since been done by the Government surveyors" (Q. J. G. Soc., viii. 175).

In 1835, the terms "Silurian" and "Cambrian" first appear in geological literature. Murchison named his system the "Silurian" in an article in the *Philosophical Magazine* for July of that year, and at the same time defined the two grand subdivisions of the system: (I.) the Upper Silurian, or the Ludlow and Wenlock beds; and (II.) the Lower Silurian, or the Caradoc and Llandeilo beds (*Phil. Mag.*, vii. 46, July 1835).

During the next month, August, the fourth meeting of the British Association was held at Edinburgh, and in the Report of the meeting (Brit. Assoc., v., August 1835), the two terms, "Silurian" and "Cambrian," are united in the title of a communication "by Prof. Sedgwick and R. I. Murchison," the title reading, "On the Silurian and Cambrian Systems, exhibiting the order in which the older sedimentry strata succeed each other in England and Wales." Murchison, after explaining his several subdivisions, said that "in South Wales" he had "traced many distinct passages from the lowest member of the "Silurian system" into the underlying slaty rocks now named by Prof. Sedgwick the Upper Cambrian." Sedgwick spoke of his "Upper Cambrian group" as including the greater part of the chain of the Berwyns, where, he said, "it is connected with the Llandeilo flags of the Silurian and expanded through a considerable part of South Wales"; the "Middle Cambrian group" as "comprising the higher mountains of Caernarvonshire and Merionethshire"; the "Lower Cambrian group" as occupying the south-west coast of Caernarvonshire, and consisting of chlorite and mica schists, and some serpentine and granular limestone; and finally, he "explained the mode of connecting Mr. Murchison's researches with his own so as to form one general system."

Thus, in four years Murchison had developed the true system in the rocks he was studying; and Sedgwick likewise had reached what appeared to be a natural grouping of the rocks of his complicated area. Further, in a united paper, or papers presented together, they had announced the names Silurian and Cambrian, and expressed their mutual satisfaction with the defined limits. Neither was yet aware of the unfortunate mischief-involving fact that the two were overlapping series.

It is well here to note that *the term "Cambrian" antedates "Taconic" of Emmons by seven years;* and also that Emmons did not know—any more than Sedgwick with regard to the Cambrian—that his system of rocks was in part Lower Silurian, and of Llandeilo and Caradoc age.

In May of 1838, nearly three years later, Sedgwick presented his first detailed memoir on North Wales and the Cambrian rocks to the Geological Society.[1] Without referring to the characteristic fossils, he divides the rocks below the Old Red Sandstone, beginning below, into (I.) the Primary Stratified Groups, including gneiss, mica-schist, and the Skiddaw slates, giving the provisional name of "Protozoic" for the series should it prove to be fossiliferous, and (II.) the Palæozoic Series; the latter including (1) the Lower Cambrian (answering to Middle Cambrian of the paper of 1835), (2) the Upper Cambrian, and (3) the "Silurian," or the series so called by Murchison. Without a report on the fossils, no comparison was possible at that time with Murchison's Silurian series. Yet Sedgwick goes so far as to say that the "Upper Cambrian," which "commences with the fossiliferous beds of Bala, and includes all the higher portions of the Berwyns and all the slate-rocks of South Wales which are below the Silurian System," "appears to pass by insensible gradation into the lower division of the Upper System (the Caradoc Sandstone);" and that "many of the fossils are identical in species with those of the Silurian System."[1] Respecting the Silurian System he refers to the abstracts of Mr. Murchison's papers and "his forthcoming work."

The Protozoic division included the "Highlands of Scotland, the crystalline schists of Anglesea, and the south-west coast of Caernarvonshire." It is added: "The series is generally without organic remains; but should organic remains appear unequivocally in any part of this class they may be described as the Protozoic System."

In the later part of the same year, 1838, Murchison's "Silurian System" was published[2]—a quarto volume of 800 pages, with twenty-seven plates of fossils, and nine folded plates of stratigraphical sections, besides many plates in the text—the outcome of his eight years of work. Five hundred pages are devoted to the Silurian System.

The dedication is as follows:—

"To you, my dear Sedgwick, a large portion of whose life has been devoted to the arduous study of the older British rocks, I dedicate this work.

"Having explored with you many a tract, both at home and abroad, I beg you to accept this offering as a memorial of friendship, and of the high sense I entertain of the value of your labours."

Through Murchison's investigations here recorded, as he remarks in his introduction with reasonable satisfaction, "a complete succession of fossiliferous strata is interpolated between the Old Red Sandstone and the oldest slaty rocks." He observes as follows of Sedgwick:—"In speaking of the labours of my friend, I may truly say, that he not only shed an entirely new light on the crystalline arrangement or slaty cleavage of the North Welsh mountains, but also overcame what to most men would have proved insurmountable difficulties in determining the order and relations of these very ancient strata amid scenes of vast dislocation. He further made several traverses across the region in which I was employed; and, sanctioning the arrangement I had adopted, he not only gave me confidence in its accuracy, but enhanced the value of my work by enabling me to unite it with his own; and thus have our joint exertions led to a general view of the sequence of the older fossiliferous deposits." In accordance with these statements many of the descriptions and the very numerous sections represent the Cambrian rocks lying beneath the Silurian—though necessarily with incorrect details, since neither Murchison nor Sedgwick had then any appreciation of the actual connection between the so-called Cambrian and Silurian.

The Silurian System, as here set forth, is essentially that of Murchison's earlier paper of 1835; and through the work, as each region is taken up, the rocks of the Upper and Lower divisions, and their several subdivisions, are described in order, with a mention of the characteristic fossils. As to the relations of the two grand divisions, he says that, "although two or three species of

[1] An abstract appeared in the Proc. Geol. Soc., ii. 675, 1838. A continuation of the paper appeared in 1841, *ibid.*, iii. 541. See also Q. J. Geol. Soc., viii., 1852.

[1] Of these fossils, he had mentioned "*Bellerophon bilobatus*, *Producta sericea*, and several species of *Orthis*" as occurring in the Bala limestone, "all of which are common to the Lower Silurian System," in a syllabus of his Cambridge lectures, published in 1837.

[2] Murchison's "Silurian System" bears on its title-page the date 1839. He states in the Q. J. Geol. Soc., viii. 177, 1852, that the work was really issued in 1838. The fossil fishes of the volume were described by Agassiz, the Trilobites by Murchison, and the rest of the species by Sowerby.

shells of the Upper Silurian rocks may be detected in the Lower Silurian, *the mass of organic remains in each group is very distinct.*" Later he makes the number of identical species larger; but even the newest results do not increase it so far as to set aside Murchison's general statement of 1838.

Sedgwick, with all the light which the fossils of the "Silurian System" were calculated to throw on his Upper Cambrian series, found in the work no encroachments on his field or on his views. They were still side by side in their labours among the hitherto unfathomed British Palæozoic rocks.

In 1840 and 1841, Murchison was in Russia with M. de Verneuil and Count Keyserling, and also in Scandinavia and Bohemia, seeking to extend his knowledge of the older fossiliferous rocks and verify his conclusions; and in 1845 the great work on the "Geology of Russia and the Urals" came out, with a further display of Upper and Lower Silurian life. In his Presidential addresses of 1842 and 1843, reviewing the facts in the light of his new observations, he went so far as to say that the Lower Silurian rocks were the oldest of fossiliferous rocks, and that the fossiliferous series of North Wales seemed to exhibit no vestiges of animal life different from those of the Lower Silurian group.

Still Sedgwick made no protest. He states definitely on this point in his paper of 1852 (Q. J. Geol. Soc., viii. 153, 1852), that from 1834, the time of the excursion with Murchison, until 1842, he had accepted Murchison's conclusions, including the reference of the Meifod beds to the Caradoc or Silurian, without questioning; but that from that time, 1842, he began to lose his confidence in the stability of the *base-line* of the "Silurian System." He adds that in 1842, Mr. Salter, the palæontologist, informed him that the Meifod beds were on the same horizon nearly with the Bala beds; and he accepted this conclusion to its full extent, using the words, "if the Meifod beds were Caradoc, the Bala beds must also be Caradoc or very nearly on its parallel." Thus the inference of Murchison was adopted, and discrepancy between them deferred. And on the following page he acknowledges that all his papers of which there is any notice in the Proceedings or Journal of the Geological Society between 1843 and 1846 admit this view as to the Bala beds and certain consequences of it—"mistakes," as he pronounced them six years later, in 1852 (Q.J. Geol. Soc., viii. 154, 1852).

In 1843, Sedgwick read before the Geological Society in June, a paper entitled "An Outline of the Geological Structure of North Wales," which was published in abstract in the Proceedings (iv. 251): and in November of the same year, one "On the Older Palæozoic (Protozoic) Rocks of North Wales" (from observations by himself in company with Mr. Salter), which appeared, with a map, in the Journal of the Geological Society (i. 1). The abstract in the Proceedings was prepared by Mr. Warburton, the President of the Geological Society, and the paper of the following November makes no allusion to this fact, or any objection to the abstract.

A remarkable feature of the November paper is that it nowhere contains the term "Upper Cambrian" or even "Cambrian," although the rocks are Sedgwick's Upper Cambrian, together with Murchison's Upper Silurian.

A second fact of historical interest is the use of the term "Protozoic," not in the sense in which it was introduced by him in 1838, but in that in which introduced in 1838 by Murchison, on p. 11 of his "Silurian System," where he says:—

"But the Silurian, though ancient, are not, as before stated, *the most* ancient fossiliferous strata. They are, in truth, but the upper portion of a succession of early deposits which it may hereafter be found necessary to describe under one comprehensive name. For this purpose I venture to suggest the term 'Protozoic Rocks' thereby to imply the first or lowest formations in which animals or vegetables appear."

These facts are in accordance with Sedgwick's acknowledgment, already mentioned.

The map accompanying the paper as originally prepared, had colours corresponding to five sets of areas, those of the "Carboniferous Limestone," "Upper Silurian," "Protozoic Rocks," "Mica and Chlorite Slate," "Porphyritic Rocks"; and here again Cambrian, Upper or Lower, does not appear, the term Protozoic being substituted. The map, as it stands in the Journal of the Geological Society, has, in place of simply "Protozoic," the words "Lower Silurian (Protozoic)." Sedgwick complains, in his paper of 1852, pp. 154, 155, of this change from his manuscript, and attributes it to Mr. Warburton, saying that "the map with its explanations of the colours plainly shows that Mr. Warburton did not comprehend the very drift and object of my paper." "I gave one colour to this whole Protozoic series only because I did not know how to draw a clear continuous line on the map between the Upper Protozoic (or Lower Silurian) rocks and the Lower Protozoic (or Lower Cambrian) rocks." "Nor did I ever dream of an incorporation of all the Lower Cambrian rocks in the system of Siluria." Sedgwick also says on the same point: "I used the word 'Protozoic' to prevent wrangling about the words Cambrian and Silurian." But this is language he had no disposition to use in 1843, as the paper of 1843 shows.

Page 155 has a footnote. In it the aspect of the facts is greatly changed. He takes back his charges, saying, "I suspect that, in the explanation of the blank portion of the rough map exhibited in illustration of my paper I had written 'Lower Silurian and Protozoic,' and that Mr. Warburton, erroneously conceiving the two terms identical, changed the words into Lower Silurian (Protozoic)." "I do not by any means accuse Mr. Warburton of any *intentional* injustice—quite the contrary; for I know that he gave his best efforts to the abstract. But he had undertaken a task for which he was not prepared, inasmuch as he had never well studied any series of rocks like those described in my papers." Sedgwick here uses Protozoic in the Sedgwick sense, not, as above, in the Murchison sense. Sedgwick again, in 1854, speaks of "the tampering with the names of my reduced map." But these explanations of his should take the harshness out of the sentence, as it was in 1843 to 1846 out of all his words.

The paper has further interest in its long lists of fossils in two tables: (I.) "Fossils of the Older Palæozoic (Protozoic) Rocks in North Wales, by J. W. Salter and J. de C. Sowerby," showing their distribution; and (2) "Fossils of the Denbigh Flagstone and Sandstone Series."

Thus, until 1846, no serious divergence of views had been noted by Sedgwick. This is manifested in his paper on the "Slate-rocks of Cumberland," read before the Geological Society on January 7 and 21, 1846 (Q. J. Geol. Soc., ii. 106, 122, 1846), which says, on the last page but one: "Taking the whole view of the case, therefore, as I know it, I would divide the older Palæozoic rocks of our island into three great groups—(3) the upper group, *exclusively Upper Silurian;* (2) the middle group, or *Lower Silurian*, including Llandeilo, Caradoc, and perhaps Wenlock; (1) the first group, or *Cambrian;*" differing in this arrangement from Murchison only in the suggestion about the Wenlock. The italics are his own. He adds:—

"This arrangement does no violence to the Silurian system of Sir R. Murchison, but takes it up in its true place; and I think it enables us to classify the old rocks in such a way as to satisfy the conditions both of the fossil and physical as well as mineralogical development."

But before the year 1846 closed, not only the overlapping of their work was recognized, but also the consequences ahead, and divergence of opinion began.

In December a paper was presented by Sedgwick to the Geological Society, on "The Fossiliferous Slates of North Wales, Cumberland, Westmoreland, and Lancashire" (Q. J. Geol. Soc., iii. 133, December 1846), which contains a protest against the downward extension of the Silurian so as to include the Cambrian. It is excellent in spirit and fair in argument. Many new facts are given respecting sections of the rocks in South Wales and North Wales, in some of which occur the Lingula flags, and characteristic fossils are mentioned. In describing some South Wales sections, Sedgwick uses the term "Cambro-Silurian" to include, beginning below: (1) "conglomerates and slates, (2) Lower Llandeilo flags, (3) slates and grits (Caradoc sandstone of Noeth Grug, &c.), (4) Upper Llandeilo flag, passing by insensible gradations into Wenlock shale." The Cambrian series is made to include: (1) the Festiniog or Tremadoc group; (2) roofing-slates, &c., the "Snowdonian group," fossiliferous in Snowdon, &c.; (3) the Bala group; and then (4) "the Cambro-Silurian group," comprising "the lower fossiliferous rocks east of the Berwyns between the Dee and the Severn—the Caradoc sandstone of the typical country of Siluria—and the Llandeilo flags of South Wales, along with certain associated slates, flags, and grits." The extension of the term Silurian down to the Lingula flags, or beyond, is opposed, because the beds below the Llandeilo are not part of the Silurian system; the term Silurian [derived from the Silures of South-East Wales and the adjoining part of England] is not geographically applicable to the Cambrian rocks; and because the only beds in North Wales closely comparable "with the Llandeilo flags are at the top of the whole Cambrian series." This last reason later lost its value when it was proved, as Sedgwick recognized years afterward, that Murchison's Llandeilo flags were really older than Sedgwick's Bala rocks.

Sedgwick's paper was followed, on January 6, with one by Murchison (Q. J. Geol. Soc., iii. 165, January 1847) objecting to this absorption of the Lower Silurian, and reiterating his remark of 1843 that the fossiliferous Cambrian beds were Lower Silurian in their fossils, and arguing, thence, for the absorption of the Cambrian, to this extent, by the Silurian. Having, eight years before, in his great work on the "Silurian System," described the Lower Silurian groups with so much detail, and with limits well defined by sections and by long lists of fossils, over a hundred species in all, many of them figured as well as described, and having thus added a long systematized range of rocks to the lower part of the Palæozoic series, he was naturally unwilling to give up the name of Lower Silurian for that of Upper Cambrian or Cambro-Silurian. Moreover, the term "Silurian," with the two subdivisions of the system, the Upper and Lower, had gone the world over, having been accepted by geologists of all lands as soon as proposed, become affixed to the rocks to which they belonged, and put into use in memoirs, maps, and geological treatises.

In 1852, the controversy, begun by encroachments not intended on either part, reached its height. Sedgwick's earnest presentation of the case (Q. J. Geol. Soc., viii. 152), and appeal before the Geological Society in February of that year—making the latter part of a memoir by him on the "Classification and Nomenclature of the Lower Palæozoic Rocks of England and Wales"—argues, like that of 1846, for the extension of the Cambrian from below upward to include the Bala beds, and thereby also the Llandeilo flags and Caradoc sandstone, although he says, "my friend has published a magnificent series of fossils from the Llandeilo flagstone." Sedgwick also expresses dissatisfaction with Mr. Warburton's abstract of his paper of June 1843, and with the change made in his map of November 1843, but, as shown above, he has no blame for Murchison and little for Mr. Warburton. He also points out some errors in the stratigraphical sections of the "Silurian System"—since the publication of which fourteen years had passed. He closes with the words (p. 168):—

"I affirm that the name 'Silurian,' given to the great Cambrian series below the Caradoc group, is historically unjust. I claim this great series as my own by the undoubted right of conquest; and I continue to give it the name 'Cambrian' on the right of priority, and, moreover, as the only name yet given to the series that does not involve a geographical contradiction. The name 'Silurian' not merely involves a principle of nomenclature that is at war with the rational logic through which every other Palæozoic group of England has gained a permanent name, but it also confers the presumed honour of a conquest over the older rocks of Wales on the part of one who barely touched their outskirts, and mistook his way as soon as he had passed within them.

"I claim the right of naming the Cambrian rocks because I flinched not from their difficulties, made out their general structure, collected their fossils, and first comprehended their respective relations to the groups above them and below them, in the great and complicated Palæozoic sections of North Wales. Nor is this all,—I claim the name Cambrian, in the sense in which I have used it, as a means of establishing a congruous nomenclature between the Welsh and the Cumbrian mountains, and bringing their respective groups into a rigid geological comparison; for the system on which I have for many years been labouring is not partial and one-sided, but general and for all England."

Sedgwick does not seem to have recognized the fact that Murchison had the same right to extend the Silurian system to the base of the Llandeilo beds, whatever its horizon, that he had to continue the Cambrian to the top of the Bala beds.[1]

Murchison's reply was made at the meeting of the Geological Society in June (Q. J. Geol. Soc., viii. 173, 1852). He remarked, with regard to Sedgwick's allusion to the excursion of 1834, that, "if I lost my way in going downward into the region of my friend, it was under his own guidance; I am answerable only for Silurian and Cambrian rocks described and drawn as such within my own region."

In his closing remarks Murchison says:—

"I am now well pleased to find that, with the exception of my old friend, all my geological contemporaries in my own country adhere to the unity of the Silurian System, and thus sustain its general adoption.

"No one more regrets than myself that Cambrian should not have proved, what it was formerly supposed to be, more ancient than the Silurian region, and thus have afforded distinct fossils and a separate system; but as things which are synonymous cannot have separate names, there is no doubt that, according to the laws of scientific literature, the term 'Silurian' must be sustained as applied to all the *fossiliferous* rocks of North Wales.

"Lastly, let me say to those who do not understand the nature of the social union of the members of the Geological Society, that the controversy which has prevailed between the eloquent Woodwardian Professor and myself has not for a moment interrupted our strong personal friendship. I am indeed confident we shall slide down the hill of life with the same mutual regard which animated us formerly when climbing together many a mountain both at home and abroad."

Murchison was right in saying that all British geologists were then with him, even in the extension of the name Silurian to the lower fossiliferous Cambrian rocks; and this was a chief source of irritation to Sedgwick. It was also, with scarcely an exception, true of geologists else-

[1] One important fact is pointed out in this paper in a letter from M'Coy, on p. 143—that the May Hill group, which Murchison had referred to the Caradoc series, really belonged by its fossils to the Upper Silurian. This point was the subject of a paper by Sedgwick in the next volume (vol. ix.) of the Journal of the Geological Society.

where. This state of opinion was partly a consequence of Murchison's early and wonderfully full description of the Silurian rocks and their fossils, which made his work a key to the Lower Palæozoic of all lands. Sedgwick's Cambrian researches and the palæontology of the region were not published in full before the years 1852–55, when appeared his "Synopsis of the Classification of the British Palæozoic Rocks," along with M'Coy's "Descriptions of British Palæozoic Fossils."

But this general acceptance was further due to the fact that the discovered fossils of the Cambrian, from the Lingula flags downward, or the "Primordial," were few, and differed not more from Silurian forms than the Silurian differed among themselves; and also, because the beds were continuous with the Silurian, without a break. Geologists under the weight of the evidence, American as well as European, naturally gravitated in the Murchisonian direction, while applauding the work of Sedgwick.

In 1853, Mr. Salter showed, by a study of the fossils (Q. J. Geol. Soc., x. 62), that the Bala beds from Bala in Merioneth, the original Bala, were included within the period of the Caradoc. Sedgwick subsequently (in the preface to the Catalogue of the Woodwardian Museum by J. W. Salter) divided his Upper Cambrian into (1) the Lower Bala, to include the Llandeilo flags (Upper Llandeilo of the Geological Survey, the Arenig being the Lower); (2) the Middle Bala, corresponding to the Caradoc sandstone, the Bala rocks, and the Coniston limestone (Geological Survey); and the Upper Bala or the Caradoc shales, Hirnant limestone, and the Lower Llandovery (cited from Etheridge, in Phillips's "Geology," ii. 77, 1885).

In 1854, the Cambrian system not having secured the place claimed for it, Sedgwick brought the subject again before the Geological Society. Besides urging his former arguments, he condemned Murchison's work so far as to imply that none of his sections "give a true notion of the geological place of the groups of Caer Caradoc and Llandeilo"; and to speak of the Llandeilo beds, in a note, as "a remarkable fossiliferous group (about the age of the Bala limestone) of which the geological place was entirely mistaken in the published sections of the Silurian System." There were errors in the sections, and that with regard to the May Hill group was a prominent one; but this was sweeping depreciation without new argument; and, in consequence of it, part of the paper was refused publication by the Geological Society.

The paper appeared in the *Philosophical Magazine* for 1854 (fourth series, vol. viii. pp. 301, 359, 481). It contains no bitter word, or personal remark against Murchison. Sedgwick was profoundly disappointed on finding, when closing up his long labours, that the Cambrian system had no place in the geology of the day. He did not see this to be the logical consequence of the facts so far as then understood. It was to him the disparagement and rejection of his faithful work; and this deeply moved him, even to estrangement from the author of the successful Silurian system.

Conclusion.

The ground about which there was reasonably a disputed claim was that of the Bala of Sedgwick's region and the Llandeilo and Caradoc of Murchison's. Respecting this common field, long priority in the describing and defining of the Llandeilo and Caradoc beds, both geologically and palæontologically, leaves no question as to Murchison's title. Below this level lie the rocks studied chiefly by Sedgwick; and if a dividing horizon of sufficient geological value had been found to exist, it should have been made the limit between a Cambrian and a Silurian system.

The claim of a worker to affix a name to a series of rocks first studied and defined by him cannot be disputed. But science may accept, or not, according as the name is, or is not, needed. In the progress of geology, the time finally was reached, when the name Cambrian was believed to be a necessity, and "Cambrian" and "Silurian" derived thence a right to follow one another in the geological record.

"To follow one another;" that is, directly, without a suppression of "Silurian" from the name of the lower subdivision by intruding the term "Ordovician," or any other term. For this is virtually appropriating what is claimed (though not so intended), and does marked injustice to one of the greatest of British geologists. Moreover, such an intruded term commemorates, with harsh emphasis, misjudgments and their consequences, which are better forgotten. Rather let the two names, standing together as in 1835, recall the fifteen years of friendly labours in Cambria and Siluria and the other earlier years of united research.

JAMES D. DANA.

THE WEATHER IN JANUARY.

THE month of January, which is generally the coldest month of the year, was so exceptionally warm this year, and in other ways the whole period was so unusual, that a few of the leading features in connection with the weather may not be without interest. The month opened with a short spell of frost, but, after the first few days, mild weather set in, and continued until the close of the month.

The stations used by the Meteorological Office in the compilation of the Daily Weather Report scarcely represent sufficiently the weather at inland stations, but yet they will give an approximate idea of the prevailing conditions. These reports show that the warmest weather was experienced in the south-western parts of the Kingdom, the stations in the north-east of Scotland being about 5° colder than in the south-west of England. On the east coast the mean temperatures of Wick, Aberdeen, Spurn Head, and Yarmouth were each about 41°·0.

The following table gives the mean temperature results for a number of stations in all parts of the British Islands:—

Station.	Mean of max. and min.	Difference from average 15 years, 1871–1885.	Mean maximum.	Difference from average 15 years, 1871–1885.	Mean minimum.	Difference from average 15 years, 1871–1885.	Number of days with 50° and above.	Number of nights with 32° and below.
Wick	40·5	+2·8	45·2	+3·0	35·7	+2·7	4	8
Nairn	41·6	+4·3	47·1	+5·2	36·1	+3·4	13	4
Aberdeen	41·1	+3·2	45·6	+3·2	36·5	+3·2	7	4
Leith	42·2	+3·0	48·2	+3·6	36·2	+2·5	15	9
Shields	42·3	+3·4	47·8	+4·7	36·8	+2·1	14	5
York	41·8	+3·6	47·9	+4·7	35·6	+2·5	15	8
Loughborough	42·2	+4·0	48·4	+4·9	36·0	+3·1	17	6
Ardrossan	43·6	+3·2	47·3	+2·9	39·8	+3·4	6	3
Donaghadee	42·6	+2·2	47·7	+3·3	37·5	+1·2	15	2
Holyhead	44·7	+2·2	48·7	+2·8	40·7	+1·7	18	0
Liverpool	43·2	+3·4	48·5	+4·6	37·8	+2·2	16	4
Parsonstown	42·2	+1·9	48·8	+2·8	35·5	+0·9	16	7
Valencia	45·6	+0·4	51·1	+1·3	40·0	−0·5	21	3
Roche's Point	45·7	+1·9	50·2	+2·3	41·2	+1·5	23	1
Pembroke	46·0	+3·1	49·2	+3·4	42·8	+2·9	17	0
Scilly	48·3	+2·1	51·5	+2·4	45·0	+1·7	25	0
Jersey	46·6	+4·2	50·5	+4·5	42·6	+3·9	24	1
Hurst Castle	45·4	+4·2	49·8	+4·5	40·9	+3·9	23	2
London	43·7	+4·1	49·5	+4·7	37·8	+3·4	20	5
Oxford	42·5	+3·4	48·1	+4·3	36·8	+2·4	15	4
Cambridge...	41·9	+3·6	48·9	+5·0	34·9	+2·3	19	10
Yarmouth	40·8	+2·6	45·6	+3·7	36·0	+1·5	6	7

From this it is seen that the excess of temperature was least at the extreme western stations, the mean at Valencia only exceeding the average for 15 years by 0°·4, whilst the night temperature was even below the average. In nearly every case it is seen that the excess of the day temperatures over the average was larger than that of the night temperatures. A feature of especial interest in the table is the large number of days on which the temperature reached 50° or above.

It is interesting to notice the very great difference between the temperature in January this year, in comparison with that which occurred in January 1881, when the weather was exceptionally cold. At Loughborough, the mean temperature this year exceeded that in 1881 by 17°, which is 4° in excess of the difference between the average temperature for January and May; there were also several stations in nearly all parts of the Kingdom with an excess of 12° and 13°.

At Greenwich Observatory the mean temperature obtained from the mean of the maximum and minimum readings was 43°·4; and with the exception of 43°·5 in 1884 and 43°·6 in 1846, this has not been exceeded in January during the last half-century. The mean of the highest day temperatures was 48°·5, which is higher than any January during the last fifty years, and the only other instances of 48°, or above, were 48°·1 in 1877 and 1851, and 48°·0 in 1846. There were six years with the mean maximum between 47° and 48°, but only eighteen in all above 45°, whilst in January 1879 the mean of the maxima was only 35°·1, or 13°·4 colder than this year, and in 1881 it was only 36°·2. There have been three Januaries during the last half-century with a higher mean night temperature, but in no year was the excess more than 1.° In January this year the mean minimum was 38°·2, and in 1884 it was 39°·2. The Greenwich observations also show that there were in January 17 days with a temperature of 50° or above, whereas in the corresponding period during the last 50 years there has been no similarly high number of days with this temperature. It was reached 14 times in 1877, 1853, and 1846; 13 times in 1873 and 1849; 12 times in 1884; 11 times in 1874, 1869, 1852, and 1851; and in 28 Januaries 50° or above was only attained 5 times or less.

The warm weather was very intimately connected with the heavy wind storms which occurred throughout the month, the storm systems which so frequently arrived on our coasts from off the Atlantic being the natural carriers of warm moist air. Scarcely a day passed during the month without the arrival of some fresh disturbance from the westward, but with one or two exceptions the central areas of the storm systems skirted the western and northern coasts and did not pass directly over our islands. The disturbances, however, passed sufficiently near to us to cause winds of gale force, and there was scarcely a day throughout the month that a gale was not blowing in some part of the United Kingdom. In the North Atlantic the month was exceptionally stormy, and vessels trading between Europe and America experienced unusually heavy weather.

The month was also marked by the prevalence of influenza, and, in addition to this, a general unhealthiness pervaded all classes of the community. The death-rate, from all causes, in London, for the four weeks ending January 25, corresponded to an annual rate of 29·7 per 1000 of the total population, which is excessively high. The rates for the corresponding period in the last four years were 21·7 in 1889, 23·2 in 1888, 22·7 in 1887, and 22·6 in 1886.

CHAS. HARDING.

NOTES.

THE subject of the Bakerian Lecture, which, as we announced last week, is to be delivered by Prof. Schuster on March 20, will be "The Discharge of Electricity through Gases."

THE Academy of Sciences of Berlin has presented the following sums of money: £90 to Dr. Rohde, of Breslau, for a journey to Naples to continue his observations on the central nervous system of sharks and echinoderms at Prof. Dohrn's zoological station; £80 to Prof. Matthiessen, of Rostock, to further his researches on the eyes of whales at the stations of the North Sea fisheries; £25 to Prof. Dr. Winkler, of Breslau, for a journey to St. Petersburg to make researches on the Turkish, Samoyed, and Tungusian languages; £30 to Dr. Schellong, the New Guinea traveller, to publish the results of his anthropological studies.

IT is proposed that the following address shall be presented to Prof. Stuart on the occasion of his resignation of his Professorship at Cambridge:—"We, the undersigned resident members of the Senate, having learned from your letter to the Vice-Chancellor your intention of resigning your Professorship in the University, desire to express our sense of the great public service which you have rendered in connection with the University Extension movement. By yourself first delivering specimen courses of lectures, and afterwards strenuously advocating and ably organizing their wide-spread establishment, you did for the country at large, and for our own and other Universities, work which we regard with sincere respect and admiration. The degree in which Cambridge has, during the last twenty years, come into useful relations with sections of the community which were previously regarded as beyond the sphere of its influence is, we hold, largely attributable to your inspiring initiative, and to the wise principles of administration which, mainly under your guidance, the University laid down."

AMONG the lectures to be delivered at the Royal Institution of Great Britain after Easter we note the following:—On Tuesdays, April 15, 22, 29, three lectures on the place of Oxford University in English history, by the Hon. George C. Brodrick; on Tuesdays, May 27, June 3, 10, three lectures on the natural history of society, by Mr. Andrew Lang; on Thursdays, April 17, 24, May 1, three lectures on the heat of the moon and stars (the Tyndall Lectures), by Mr. C. V. Boys, F.R.S.; on Thursdays, May 8, 15, 22, 29, June 5, 12, six lectures on flame and explosives, by Prof. Dewar, F.R.S.; on Saturdays, April 19, 26, May 3, three lectures on colour and its chemical action, by Captain W. de W. Abney, F.R.S.

THE De Candolle Prize has been awarded to Prof. F. Buchenau, of Bremen, for his monograph of the Juncagineæ.

A CONGRESS for Viticulture will be held in Rome from the 23rd to the 27th of the present month. The principal object of the Congress will be the discussion of remedies for the *Peronospora viticola* and other diseases of the vine caused by vegetable parasites. There will be an International Exhibition of apparatus for the cure of these diseases, and numerous prizes will be awarded.

THE annual general meeting of the members of the German Botanical Society is to be held this year in Bremen late in September.

APPENDIX I. of the *Kew Bulletin*, just issued, contains a list of such hardy herbaceous annual and perennial plants and of such trees and shrubs as matured seeds under cultivation in the Royal Gardens, Kew, during the year 1889. It is explained that these seeds are available for exchange with Colonial, Indian, and Foreign Botanic Gardens, as well as with regular correspondents of Kew. The seeds are for the most part only available in moderate quantity, and are not sold to the general public.

THE Nachtigal Gesellschaft of Berlin, for German research in Africa, has just completed its second year of business. It was announced at the last general meeting that the list of members

had been doubled during the last year. The Society's library contains 200 books on Africa. Herr Schiller-Tietz was elected President of the Society in place of Councillor Engelke.

A CURIOUS phenomenon is reported from Batoum. On January 23, at 4 p.m., during a complete calm, the sea is said to have suddenly receded from the shore, leaving it bare to a depth of ten fathoms. The water of the port rushed out to sea, tearing many of the ships from their anchorage, and causing a great amount of damage. After a short time the sea assumed its usual level.

AN important addition to our knowledge of the meteorology of Central America has been made by the publication of Parts 1–4 of the *Boletin trimestral* of the National Meteorological Institute of San José, Costa Rica, for the year 1888, under the direction of Prof. E. Pittier. The Observatory is situated in latitude 9° 56′ N., longitude 84° 8′ W., and its importance may be judged from the fact that no other station of the first order possessing self-recording instruments is to be found between Mexico, in latitude 19° N., and Rio de Janeiro, in latitude 23° S. The bulletin contains observations made several times daily, and hourly observations of rainfall for five months, also a summary of the observations formerly made in Costa Rica. The older series of observations show that the mean yearly extremes of temperature at San José were 78°·8 and 56°·7, while the mean difference of the monthly means amounted only to about 4°. The daily period of rainfall is very marked. From sunrise to noon scarcely any rain falls, while between noon and 6h. p.m. about 75 per cent. of the whole amount falls. The mean duration of rain on a wet day is 2h. 9m. Only two months of anemometrical observations are given; these show that the maximum velocity at noon is twice as great as the mean velocity during the night. An interesting summary of the observations has been published by Dr. Hann in the *Meteorologische Zeitschrift* for February.

AT a recent meeting of the Paris Geographical Society an interesting lecture was delivered by Dr. Hamy, on the history of scientific missions in France under the old monarchy. He commenced practically with the reign of Francis I., and described many missions abroad, with purely scientific aims, which are now either forgotten, or the results of which have never been published. Thus, the apothecary to Henri IV. went all over the globe in search of the peculiar products of each country, especially medicinal and food plants; still earlier, another explorer went to Brazil to study dyeing woods; and, in the last century, Condamine, Dombey, Bougainville, and La Pérouse went on their well-known expeditions. The President, Comte de Bisemont, mentioned that there were still in the archives of the Ministry of Marine copies of the instructions given to travellers and navigators in past centuries, and that these were "positively models of their kind, which could not be followed too closely now." Prof. Bureau, of the Museum of Natural History in Paris, observed that a botanical collection made by Paul Lucas in the reign of Louis XIV. still existed in the Museum, and he referred especially to Tournefort, of the same period, whom he described as the scientific traveller of former times who perhaps most nearly approached moderns in his methods of observation. He was sent by the King on a botanical expedition to the Levant, with very precise instructions, amongst others, to collect and observe the plants mentioned by the ancients. He did not confine himself to this, but formed a complete herbarium, which is still preserved at the Museum, and is one of its treasures. He was accompanied by an artist named Aubriet, who brought back a large collection of coloured sketches, which forms an important part of the unrivalled collection in the library of the Museum.

A NEW and very simple method of measuring small elongations of a bar under any influence has been devised by Signor Cardani (*Cosmos*). To one end of the bar is attached a metallic wire stretched so as to give a determinate number of vibrations. When the bar expands, the wire becomes less tense, and gives fewer vibrations, and there is a simple relation between the number of vibrations and the elongation of the bar. The author cites a case in which a variation of one hundredth of a millimetre in a bar lessens the double vibrations from 99 to 96·5. Now, a practised ear will appreciate a difference of one vibration per cent.; hence it suffices to ascertain variations of length less than 0·01 millimetre. With other methods of measuring change of vibration, elongations of thousandths of a millimetre may be ascertained.

THE first careful determination of latitude in Tokio (according to the *Japan Weekly Mail*) was made in 1876 by Captain Kimotsuki, at that time Director of the Naval Observatory. In 1888, soon after the transfer of the Naval Observatory to the Imperial University, and its reorganization as the Astronomical Observatory of Tokio, the new Director, Prof. Terao, resolved upon a redetermination of the latitude. The work was entrusted to Mr. Watanabe, a skilled observer, and the result has been published as the first of the "Annales de l'Observatoire Astronomique de Tokio (Université Impériale du Japon, Collège des Sciences)." The determination was made in two distinct ways: first, by observations of the upper and lower transits of the Pole star across the meridian; second, by observations of the zenith distances of 38 different stars, arranged in couples according to Talcott's method. This latter method only was used by Captain Kimotsuki in this earlier determination. The earlier mean value for the latitude was 35° 39′ 17″·492; while the recently obtained mean values were 35° 39′ 15″·05 by the first method, and 35° 39′ 15″·41 by the second method. This discrepancy of fully 2″ is, in the circumstances, too large to be regarded as an accidental error, and must be due to some systematic error in either the earlier or the later determination. More weight will be attached to the new determination, since Mr. Watanabe had much superior instruments at his disposal.

THE stay of some 306 natives from various French colonies, &c., for about six months, in Paris last year, in connection with the Exhibition, was an interesting experiment in acclimatization. Owing to wise hygienic measures (such as vaccination, good water-supply, isolation of closets, and surveillance of food), these Annamites, Tonquinese, Senegalese, &c., seem to have escaped most of the common endemic disease. According to the *Semaine Médicale*, they had no typhoid fever, scarlatina, or measles, though these were in Paris at the time. Some 68 natives were attacked by mumps. The fatigues of a voyage and the change of climate led to a recurrence of intermittent fever, with grave symptoms, in twenty cases. It was thought at first to be typhoid fever of a severe type; but the rapid and durable efficacy of sulphate of quinine, given in doses of 2 to 3 grammes a day, proved the paludine nature of the disorder. It is noteworthy that most illnesses of this population, especially that just noticed, and those from cold, appeared during the first part of the time, when the weather was mild; while in the second period, with unfavourable atmospheric conditions, the illness diminished, whether owing to precautions in the matter of dress and food, or to more complete acclimatization. The negroes of Senegal and the Gaboon seem to have been the greatest sufferers, while the Indo-Chinese race acclimatized the best.

THE first *Bulletin* issued this year by the Académie Royale de Belgique contains a note by M. Van Beneden, on a Ziphius which was stranded in the Mediterranean, and a list of the prize subjects for 1891. The subjects dealt with are architecture, engraving, painting, and music. Four gold medals are given, having values 1000, two 800, and 600 francs respectively. The dissertations may be written in French, Flemish, or Latin, and must be sent before June 1, 1891, to M. J. Liagre, Secretary of the Academy.

A SHORT note on diethylene diamine, $C_2H_4\langle{}^{NH}_{NH}\rangle C_2H_4$, is contributed to the new number of the *Berichte* of the German Chemical Society by Dr. J. Sieber, of Breslau. It was obtained by the action of ethylene dibromide, $C_2H_4Br_2$, upon ethylene diamine, $C_2H_4\langle{}^{NH_2}_{NH_2}$, a liquid boiling at 123° C. Upon treating the product of this reaction with caustic potash, an oily liquid separated, consisting of a mixture of bases. The separated liquid was next dehydrated as completely as possible, and then submitted to fractional distillation, when the portion boiling between 168°–175° was found to consist of diethylene diamine admixed with a little water. The affinity of the base for water is, in fact, so great that it was found impossible to remove the last traces of moisture. Diethylene diamine, however, readily forms salts which can be isolated in a state of purity, and the analyses of which prove the composition of the base itself. The hydrochloride, $C_2H_4\langle{}^{NH.HCl}_{NH.HCl}\rangle C_2H_4$, crystallizes in beautiful white needles, very soluble in water, but insoluble in alcohol. The platinochloride, $C_4H_{10}N_2(HCl)_2PtCl_4$, forms fine yellow needle-shaped crystals, readily soluble in hot water, but difficultly soluble in boiling alcohol. A very beautiful salt is also formed with mercuric chloride, $C_4H_{10}N_2(HCl)_2HgCl_2$, consisting of star-like aggregates of acicular crystals, also soluble in hot water, but reprecipitated by the addition of alcohol.

DRS. WILL AND PINNOW communicate to the same journal their report upon the analysis of the remarkable meteorite of Carcote, Western Cordilleras, Chili. The great mass of this meteorite, 80 per cent., is found to consist of two silicates. One of them is readily decomposed by hydrochloric acid, and possesses the composition and optical characters of olivine, $(MgFe)_2SiO_4$. The other is unattacked by hydrochloric acid, and exhibits the chemical and crystallographical characters of a member of the diopside group. Interspersed among the silicates are smaller quantities of chrome ironstone, bronze-like sulphide of iron, probably troilite, and light steel-grey nickeliferous iron. The latter is not only found in minute particles, but also frequently in small plates which show the Widmannstadt figures in the form of an extremely fine rectangular network. Here and there are found silver-white crystals of rhabdite, one of the forms of nickeliferous iron. By far, however, the most interesting substance contained in the meteorite, is a form of crystalline elementary carbon, dull black in appearance and of extreme hardness, at least 9. It is, in fact, a variety of black diamond, and its presence in the meteorite affords considerable ground for speculation. Carbon is further present in the form of organic substances soluble in ether, and these substances carbonize upon heating, evolving the usual odour of burning organic matter. Hence this meteorite is an extremely interesting one, and forms another addition to the fast-accumulating list of those in which carbon forms a not insignificant ingredient.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on March 6 = 8h. 58m. 19s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 1713	—	—	8 45 49	+33 50
(2) 120 Schj.	6·5	Reddish-yellow.	9 4 6	+31 26
(3) α Hydræ	3	Yellow.	9 22 12	− 8 11
(4) ι Cancri	4	Yellowish-white.	8 52 30	+12 17
(5) 124 Schj.	5·4	Reddish-yellow.	9 45 59	+22 36
(6) T Monocerotis ...	Var.	Yellow.	6 19 20	+ 7 8·7

Remarks.

(1) This bright oval nebula is now in a very convenient position for observation. I am not aware that the spectrum has been recorded. It is about 8′ long, and 3′ broad, and is thus described in the General Catalogue: "Very bright, very large, very much elongated 40°·9, gradually much brighter in the middle." The description is very suggestive of the Great Nebula in Andromeda, and if, as in that case, the spectrum at first appears continuous, closer scrutiny may reveal irregularities. The brighter parts, assuming that they exist, should be compared with the spectrum of carbon.

(2) According to the observations of D'Arrest, Secchi, and Vogel, this is a fine example of the stars of Group II. Dunér states that all the bands 1 to 10 inclusive are excessively wide and dark, and that the spectrum is totally discontinuous. The star, therefore, affords a good opportunity for further observations of the bright carbon flutings with the object of establishing the cometary character of the stars of this group. It may be remarked that the citron band of carbon need not enter into this comparison, as it will be masked by the dark fluting of manganese (band 4).

(3) A star of the solar type (Konkoly). The usual differential observations are required.

(4) A star of Group IV. (Vogel). The usual observations are required.

(5) This star has a "very fine" spectrum of the Group VI. type, notwithstanding its low altitude in our latitude (Dunér). The principal bands, 6, 9, and 10, are very dark, and the secondary bands, 4 and 5, are also well seen. Further observations, with special reference to line or other absorptions, are suggested.

(6) A maximum of this short-period variable will occur on March 8. Gore gives the period as 26·76 days, and the magnitudes at maximum and minimum as 6·2 and 7·6 respectively. There is still a little doubt with regard to its spectrum. In his spectroscopic catalogue, Vogel writes it II.*a*? III.*a*, giving the magnitude at the time of observation as 7·3. In all probability the spectrum is intermediate between Group II. and Group III., perhaps something like Aldebaran. A. FOWLER.

THE TOTAL SOLAR ECLIPSE OF DECEMBER 22, 1889.—M. A. De La Baume Pluvinel, who was located in Royal Island, about 30 miles north of Cayenne, during this eclipse, communicated his results to the Paris Academy on the 17th ult. (*Comptes rendus*, No. 7, 1890). An examination of the photographs of the corona which were obtained leads to the conclusions that—

(1) The corona presented the same general aspect as on January 1, 1889.

(2) The extension of the corona was small, being about 18′ at the solar equator, and about 6′ at the poles, and in this respect resembled the coronæ of 1867 and 1878, thus confirming the intimate relation that exists between the intensity of extra-solar phenomena and the frequency of sun-spots.

(3) The aspect of the luminous aigrettes which constitute the corona, and notably the curved form of the aigrettes in the neighbourhood of the poles, seem to prove the existence of streams of matter submitted to two forces—a force of projection normal to the solar sphere, and a centrifugal force developed by the sun's rotation.

COMETS AND ASTEROIDS DISCOVERED IN 1889.—

Comet a 1889.—Discovered on January 15, a little before dawn, by Mr. W. Brooks at Geneva, N.Y., U.S.A. The comet was moving rapidly from east to west, and was not afterwards observed.

Comet b 1889.—Discovered by Mr. Barnard, of the Lick Observatory, on March 31; it was then very feeble and difficult to see. After perihelion passage, the comet was observed at Ann Arbor on July 22, near the position assigned to it by M. E. Millosevich.

Comet c 1889.—Also discovered by Mr. Barnard, on June 23, as a faint nebulosity without condensation or tail. Not observed after August 6. Dr. Berberich determined the elements of this comet on the hypothesis of an elliptic orbit, and found that its period was 128 years.

Comet d 1889.—This comet, the most interesting of those observed last year, was discovered by Mr. Brooks, of Geneva, U.S., on July 6. It is periodic, the time of revolution being 7·04 years. On August 1, Mr. Barnard found that the principal comet was accompanied by four companions. Mr. Chandler

has found that in 1886 this comet must have approached near to Jupiter, and his investigations seem to show that it is identical with the lost comet of Lexell.

Comet e 1889.—Discovered by Mr. Davidson at Branscombe, Mackay (Queensland), on July 22, and visible to the naked eye at first as a star of the fourth magnitude. It moved rapidly towards the north, and at the same time diminished in brightness, remaining visible, however, up to November.

Comet f 1889.—Discovered by Mr. Lewis Swift at Rochester, U.S., on November 17. From observations extending over twenty days, Dr. Zelbr was led to conclude that the comet was periodic, the time of revolution being 6·91 years.

Comet g 1889.—Discovered by M. Borrelly at Marseille, on December 12. It was then feeble, but rapidly increased in brightness. Although the declination of this comet on discovery was + 48° 55′, it moved so quickly towards the south, that it was lost to our latitudes about January 10, 1890. The first observations fixed the perihelion passage at January 26, 1890.

Six asteroids were discovered in 1889, viz. :—

(282) Discovered by M. Charlois at Nice on January 28.

(284) ,, ,, ,, ,, May 29.
(285) ,, ,, ,, ,, August 3.
(286) ,, ,, M. J. Palisa at Vienna on August 3.
(287) ,, ,, Dr. Peters at Clinton, U.S., October 13.

MASS OF SATURN.—The Transactions of the Astronomical Observatory of Yale University, vol. i. part ii., contains some researches with the heliometer by Mr. Asaph Hall, for the determination of the orbit of Titan and the mass of Saturn.

From observations made at the oppositions of 1885–86, 1886–87, the mean value of the semi-major axis of Titan's orbit was determined as—

$$176''\cdot570 \pm 0''\cdot0243\,;$$

and the mass of Saturn—

$$\frac{1}{3500\cdot5 \pm 1\cdot44},$$

the sun being unity.

Struve showed that the value found by Bessel from Titan should be 3502·5, while the values found by Struve himself from Iapetus and Titan are respectively 3500·2 ± 0·82 and 3495·7 ± 1·43. Prof. Hall, with the great Washington refractor, found from Iapetus by means of differences of right ascension and declination, the mass 3481·2 ± 0·65, and by distances and position-angles 3481·4 ± 0·97 ; from Titan the values corresponding to the same methods are 3496·3 ± 1·84, and 3469·9 ± 1·49, but there seem to be grounds for questioning these results, so discordant with those found by Struve, and at Yale College.

THE OPENING OF THE FORTH BRIDGE.

MUCH interest was excited all over the country by the opening of the Forth Bridge on Tuesday. The ceremony was simple, and all the arrangements were carried out successfully. There was no rain, and although the wind blew stiffly, it was "comparatively mild." The special train conveying the directors and invited guests left the Waverley Station, Edinburgh, in two portions, the first at 10.45, the second, to which the Royal carriages were attached, ten minutes later. At the Forth Bridge Station Sir John Fowler, Mr. Benjamin Baker, Mr. William Arrol, Mr. Phillips, and other gentlemen connected with the building of the bridge, awaited the arrival of the Royal party from Dalmeny. By the special desire of the Prince of Wales, who wished to have an opportunity of examining some details of the structure, the Royal train steamed very slowly across the bridge. As seen from the shore, the long train of large saloon carriages is said to have looked like "a mere toy as it passed through the stupendous framework of tubes and girders at Inverkeithing." From the North Queensferry Pier the steam launch *Dolphin* conveyed the Royal party and the directors over the Firth, so that the bridge might be seen from the sea; and another vessel followed, containing the rest of the company. Both vessels steamed out to the middle of the Firth; and, according to the *Times*, the view was much enjoyed "as each cantilever was passed in succession, the junction of the girder bridges with the cantilever arms being specially noted." Afterwards, the bridge was recrossed, and in the middle of the north connecting girder the train stopped to allow the Prince of Wales to perform the ceremony of driving the last rivet. "A temporary wooden staging," says the *Times*, "had been erected there, and upon it His Royal Highness stepped, along with Lord Tweeddale, Lord Rosebery, and Mr. Arrol. The hydraulic rivetter was swung from one of the booms, the pressure being supplied from an accumulator at Inchgarvie. Two men were placed on the boom below to manipulate the machine. The gilded rivet having been placed in the bolt-hole, and the silver key having been handed to His Royal Highness by Lord Tweeddale, the Prince, with Mr. Arrol's assistance, finished the work in a few seconds, amid cheers. The rivet is in the outside of the boom, and holds together three plates. Around its gilded top there is an inscription stating that it is the 'last rivet, driven in by His Royal Highness the Prince of Wales, 4th March, 1890.' The train stopped a second time at the south great cantilever pier, where another platform had been erected, upon which several ladies were standing. Here the Prince again left the train, at half-past 1 o'clock, to make the formal declaration of the opening of the bridge. As the wind was blowing a perfect gale, so that His Royal Highness had difficulty in retaining a steady foothold, it was impossible to make a speech. He therefore simply said : 'Ladies and Gentlemen, I now declare the Forth Bridge open.' Hearty cheers greeted the announcement, and, the Prince having returned to his carriage, the train moved slowly along to the Forth Bridge Station."

At 2 o'clock a banquet was given in the model-room at the bridge works, the chair being occupied by Mr. M. W. Thompson. The Prince of Wales, responding to the toast of "The Prince of Wales and other members of the Royal Family," spoke as follows :—

"I feel very grateful for the kind words which have fallen from the chairman in proposing the toast, and I thank you all most heartily for the cordial way in which you have received it. The day has been a most interesting day to all of us, and especially so to me, and I feel very grateful that I have been asked to take part in so interesting and important a ceremony as the one at which we have all assisted. I had the advantage, nearly five and a half years ago, of seeing the Forth Bridge at its very commencement, and I always looked forward to the day when I should witness its successful accomplishment. I may perhaps say that in opening bridges I am an old hand. At the request of the Canadian Government I performed the opening ceremony 30 years ago of opening the Victoria Bridge over the St. Lawrence at Montreal, putting in the last rivet, the total of rivets being one million. To-day I have performed a similar ceremony for the Forth Bridge, but on this occasion the rivets number nearly eight millions instead of one million. The construction of the bridge has been on the cantilever principle, which has been known to the Chinese for ages, and specimens of it may be seen likewise in Japan, Tibet, and the North-West Provinces of India. Work of this description has hitherto been carried out on small dimensions, but in this case the engineers have had to construct a bridge in 30 fathoms of water, at the height of 150 feet above high water mark, and crossing two channels, each one-third of a mile in width. Had it not been for the intervening island of Inchgarvie the project would have been impracticable It may perhaps interest you if I mention a few figures in connection with the construction of the bridge. Its extreme length, including the approach viaduct, is 2765 yards, one and one-fifth of a mile, and the actual length of the cantilever portion of the bridge is one mile and 20 yards. The weight of steel in it amounts to 51,000 tons, and the extreme height of the steel structure above mean water-level is over 370 feet ; above the bottom of the deepest foundation 452 feet, while the rail-level above high water is 156½ feet. Allowance has been made for contraction and expansion and for changes of temperature to the extent of one inch per 100 feet over the whole bridge. The wind-pressure provided for is 56 lb. on each square foot of area, amounting in the aggregate to about 7700 tons of lateral pressure on the cantilever portion of the bridge. About 25 acres of surface will have to be painted with three coats of paint. As I have said, about eight millions of rivets have been used in the bridge, and 42 miles of bent plates used in the tubes, about the distance between Edinburgh and Glasgow. Two million pounds have been spent on the site in building the foundations and piers ; in the erection of the superstructure ; on labour in the preparation of steel, granite, masonry, timber, and concrete ; on tools, cranes, drills, and other machines required as plant ; while about two

and a half millions has been the entire cost of the structure, of which £800,000 (nearly one-third of this amount) has been expended on plant and general charges. These figures will give you some idea of the magnitude of the work, and will assist you to realize the labour and anxiety which all those connected with it must have undergone. The works were commenced in April 1883, and it is highly to the credit of everyone engaged in the operation that a structure so stupendous and so exceptional in its character should have been completed within seven years. The opening of the bridge must necessarily produce important results and changes in the railway service of the east coast of Scotland, and it will, above all, place the valuable manufacturing and mineral-producing district of Fife in immediate communication with the south side of the Firth of Forth. When the Glenfarg line, now nearly completed, is opened for traffic, the distance between Edinburgh and Perth will be reduced from 69 to 47 miles, and instead of the journey occupying, as at present, two hours and 20 minutes, an express will be able to do it in an hour. Dundee, likewise, will be brought to within 59 miles of Edinburgh, and Aberdeen 130 miles, and no sea ferries will have to be crossed. The construction of the bridge is due to the enterprise of four important railway companies—(1) North British (the bridge is in its district), (2) North-Eastern, (3) Midland, and (4) Great Northern—and the design is that of two most eminent engineers, Sir John Fowler and Mr. Benjamin Baker. The contractor was Mr. William Arrol, and the present Tay Bridge, and the bridge which I have inaugurated to-day, will be lasting monuments of his skill, resources, and energy. I have much pleasure in stating that, on the recommendation of the Prime Minister, the Queen has been pleased to create Mr. Matthew William Thompson, Chairman of the Forth Bridge Company and of the Midland Railway Company, and Sir John Fowler, engineer-in-chief of the Forth Bridge, baronets of the United Kingdom. The Queen has also created, or intends to create, Mr. Benjamin Baker, Sir John Fowler's colleague, a Knight Commander of the Order of St. Michael and St. George, and to confer on Mr. William Arrol, the contractor, the honour of a knighthood. I must not allow this opportunity to pass without mentioning the valuable assistance which has been rendered to the companies by Mr. Wieland, their able and indefatigable secretary, who deserves especial praise for the admirable way in which he has carried out the important financial arrangements essential in a scheme of such magnitude. Before concluding I must express my pleasure at seeing here Major-General Hutchinson and Major Marindin, two of the inspecting officers of the Board of Trade. Although in this country great undertakings of the kind which we are celebrating this day are wisely wholly left to the enterprise and genius of private individuals without aid or favour from the State; yet, in connection with these particular works, Parliament, I am informed, for the first time associated officers of the Board of Trade with those practically engaged in the construction of this magnificent bridge from its commencement by requiring the Board of Trade to make quarterly reports to be laid before Parliament as to the nature and progress of the works. This most important and delicate duty has been performed by Major-General Hutchinson and Major Marindin; and I now congratulate them on the completion of their responsible duties, which they have carried out in a way that redounds credit to themselves and to the department which they so ably serve. Allow me again, gentlemen, in thanking you for the kind way in which you have received this toast, to assure you of the great pleasure and gratification it has been to me to have been present on this occasion to inaugurate this great success of the skill of engineering."

Sir John Fowler, in acknowledging the toast of the Forth Bridge, said he begged to return his most grateful thanks to His Royal Highness the Prince of Wales for the flattering manner in which he had spoken of their work. It was now seven years ago since the foundations of the bridge were commenced, but up to two years ago they had to endure not only the legitimate anxieties of their duties, but the attacks and evil predictions which were always directed against those who undertook engineering work of novelty or exceptional magnitude. It was very curious to watch the manner of retreat of these prophets of failure. The results had proved them to be mistaken. But he could tell some very curious stories connected with the bridge. He pointed out how, from the nature of the materials which had been used in the construction of the bridge, and from the nationality of the men who had been engaged in that construction, the bridge possessed an international character. He also predicted that the bridge would last for many, many years, and he cordially acknowledged the workmanship and ability of all who had assisted in its erection. As to the workmen themselves, he said they had done admirable work, and had never knowingly scamped a rivet.

Mr. Arrol also acknowledged the toast, and Mr. Baker, in response to calls from the audience, made a few remarks.

Mr. John Dent, Deputy-Chairman of the Forth Bridge Railway Company, in proposing the toast of "The Guests," congratulated the recipients of the special honours bestowed by the Queen, and he spoke of the universal reputation which had become attached to the bridge, which stood as a monument of industry, of genius, and of ability.

After a clever speech from Lord Rosebery, Herr Mehrtens, of the Prussian Railway Department, replied for himself and in the name of his companions from Saxony, Austria, and Hungary. He expressed their feelings of thankfulness that they had been permitted to be present on so interesting an occasion, and their admiration at all the wonderful things they had seen that day. That day, he said, marked the commencement of a new era in iron bridge building. He congratulated Great Britain, which had led the way in iron bridge building, on now having the largest span bridge and the strongest bridge in the world.

M. Picot, on behalf of the railway engineers of France, also replied in a speech in which he eulogized the bridge and its engineers and contractors.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The General Board of Studies announce that they will this term appoint an additional Lecturer in Botany for three years, from the beginning of the Easter term 1890. The stipend is £100 a year. Names of candidates are to be sent to the Vice-Chancellor on or before March 8.

The Syndics of the Press propose that a gift of books published by them shall be made to the Library of the University of Toronto, lately destroyed by fire.

The discussion by the Senate of the proposal to accept the Newall telescope was on the whole favourable to the proposal, though the difficulty of finding the funds required for its adequate maintenance and use has not yet been made. From remarks made by members of the Observatory Syndicate, it appears that it regards the purchase of a large reflecting telescope as the first claim on the Sheepshanks Fund; and it is unwilling to deplete the fund until this purchase can be effected. Prof. Liveing referred to the recent development of astronomical physics, and said the University was bound to further it. The Newall telescope was specially suited for physical researches, and to reject it as a "white elephant" would damage the University by discouraging other benefactors. The matter is to be referred to the Financial Board.

At the meeting of the Philosophical Society on March 10, the following papers are promised:—W. Gardiner, on the germination of *Acacia sphærocephala*; M. C. Potter, the thickening of the stem in Cucurbitaceæ; Dr. Lea and W. L. Dickinson, note on the action of rennin and fibrin-ferment; W. Bateson, on some skulls of Egyptian mummified cats.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 20.—"A Comparative Study of Natural and Artificial Digestions" (Preliminary Account). By A. Sheridan Lea, Sc D., Fellow of Gonville and Caius College, Cambridge, University Lecturer in Physiology. Communicated by Prof. Michael Foster, Sec. R.S.

The objects of the investigation were (i.) to obtain in artificial digestions some closer approximation to the general conditions under which natural digestion is carried on in the body, and (ii.) to apply the improved methods of carrying on artificial digestions to the elucidation of some special differences, which so far have appeared to exist between the natural and artificial processes.

An apparatus was described by means of which digestions can be carried on in a dialyzer in such a way as to provide for the constant motion of the digesting mixture and the removal of digestive products: by this method a partial reproduction of two of the most important factors in natural digestion is provided.

So far the method has been employed for

I. *The salivary digestion of starch.* Experiments conducted under otherwise similar conditions in the dialyzing digester and a flask, showed that—(i.) The *rate* of digestion in the former is always greater than in a flask, and at the same time the tendency to the development of bacteria is greatly lessened. (ii.) The amount of starch converted into sugar is always greatest in the dialyzer. (iii.) The total sugar formed and small residue (4·29 per cent.) of dextrin left during an active and prolonged digestion in the dialyzer justify the assumption that, under the more favourable conditions existing in the body, the whole of the starch taken is converted into sugar before absorption.

The above results afford an explanation of the existing discordant statements as to the nature and amount of products formed during starch digestion.

II. *The tryptic digestion of proteids.* The experiments made dealt chiefly with the formation of leucin and tyrosin, and were undertaken, initially, in order to find out why these crystalline products are formed in large amount during an artificial digestion, while they have so far been described as occurring in mere traces during natural digestion. The results of the experiments made it probable that leucin and tyrosin should be formed during natural digestion. Examination of the contents of the small intestine during proteid digestion showed that, contrary to existing statements, leucin and tyrosin are formed in not inconsiderable quantities during the natural process.

The last part of the communication dealt with the probable physiological importance of the formation of amidated bodies during tryptic digestion, and a view was put forward as to the possible and probable importance of amides in the chemical cycle of animal metabolism.

The experiments are being extended to the pancreatic digestion of starch.

Linnean Society, February 20.—W. Carruthers, F.R.S., President, in the chair.—Mr. G. C. Druce exhibited specimens of *Agrostis canina*, var. *Scotica*, and a small collection of flowering plants dried after treatment with sulphurous acid and alcohol, and showing a partial preservation of the natural colours of the flowers.—Mr. F. P. Pascoe exhibited a series of Coleopterous and Lepidopterous insects to show the great diversity between insects of the same family.—The Right Hon. Sir John Lubbock, Bart., M.P., P.C., then gave an abstract of four memoirs which he had prepared: (1) on the fruit and seed of the Juglandiæ; (2) on the shape of the oak-leaf; (3) on the leaves of Viburnum; and (4) on the presence and functions of stipules. An interesting discussion followed, in which Mr. J. G. Baker, Mr. John Fraser, Mr. D. Morris, and Prof. Marshall Ward took part.

EDINBURGH.

Royal Society, February 17.—Sir W. Thomson, President, in the chair.—Prof. Crum Brown communicated a paper, by Mr. Tolver Preston, on Descartes' idea of space and Sir W. Thomson's theory of extended matter.—The following communications from the chemical laboratory of the University were read:—(*a*) Prof. Crum Brown, on a new synthesis of dibasic organic acids. The method proposed was the electrolysis of potassium ethyl salts of lower dibasic acids which would take place according to the scheme

$$2EtOOC.R''.COOK = EtOOC.R''.R''.COOEt + 2CO_2 + 2K,$$

thus giving the diethyl ether of a higher acid of the same series. (*b*) Prof. Crum Brown and Dr. James Walker, on the electrolysis of potassium ethyl malonate, and potassium ethyl succinate. The reaction actually takes place in great measure in the above indicated sense, the yields of pure succinic ether and of adipic ether respectively being from 20 to 30 per cent. of the theoretically obtainable quantities. The method is thus proved to be of practical as well as of theoretical importance. (*c*) Dr. John Gibson, on the action of bromine and carbonate of soda in solutions of cobalt and nickel salts.—Mr. W. Calderwood read a paper on the swimming bladder and flying powers of *Dactylopterus volitans.*

PARIS.

Academy of Sciences, February 24.—M. Hermite in the chair.—The proofs of the separation of the south-east extremity of the Asiatic continent during recent times, by M. Émile Blanchard. The author advances proofs from the resemblance of animal and vegetable life in Further India, on the peninsula of Malacca, and Sunda Islands.—The *Dryopithecus*, by M. Albert Gaudry. The relation of *Dryopithecus* to the ape and to man has been investigated.—A contribution to the chemical study of the truffle, by M. Ad. Chatin. The researches have been directed to the quantitative determination of the organic and other matter in truffles.—Scrotal pneumocèles, by M. Verneuil.—On the anatomy and the physiological pathology of the retention of urine, by M. F. Guyon.—Transformations in kinematic geometry, by M. A. Mannheim.—On the constitution of the line spectra of elements, by M. J. R. Rydberg. This is a note on the periodic recurrence of doubles and triplets in the spectrum of an element. It is shown how this periodicity enables the spectrum of an element to be found by interpolation when the spectra of elements of the same group are known, the case of gallium being given as an example of the verification of the principle.—Electrical oscillations in rarefied air, without electrodes; demonstration of the non-conductivity of the vacuum, by M. James Moser. It is well known that vacuum-tubes become luminous when near an induction coil in action. The author, by enveloping one vacuum-tube with another, in which the rarefaction could be varied, finds that the excitation may take place without any electrode. If the pressure in the outer tube be equal to 760 mm., the inner tube, under the influence of the coil, becomes luminous and of a clear blue colour; if, however, the pressure be diminished to 1 mm. of mercury, the air in the outer tube becomes luminous and of a pronounced red colour, thus reversing the phenomena.—Upon the variation, with the temperature, of the bi-refractions of quartz, barytes, and kyanite, by MM. Er. Mallard and H. Le Chatelier. This variation has been studied by the aid of a photographic spectroscopic method: with quartz a singular point is detected at 570°, at which temperature the law of variation suddenly changes; a similar phenomenon is indicated as occurring in the case of kyanite somewhere between 300° and 600°.—The vapour-pressure of acetic acid solutions, by MM. F. M. Raoult and A. Recoura. It has been previously shown by one of the authors (*Comptes rendus*, May 23, 1887; *Annales de Chimie et de Physique*, 6th series, t. xv., 1888) that, if f represents the vapour-tension of a solvent for a certain temperature, f' the vapour-tension under similar conditions when a non-volatile body is in solution, P the weight of substance dissolved in 100 grms. of the solvent, M the molecular weight of the dissolved body, and M′ the molecular weight of the solvent, then for dilute solutions—

$$K = \frac{100(f - f')}{f'P} \cdot \frac{M}{M'},$$

K being a constant generally near to unity. Employing the dynamical method, the mean value of K for acetic acid is found to be 1·61, taking 60 as the molecular weight of acetic acid; but if the molecular weight of a liquid be the same as that of the saturated vapour, the apparent anomaly disappears, for with molecular weight 97 (deduced from density of saturated acetic acid vapour at 118°, viz. 3·35), the above formula gives K = 1.—The action, in the dry way, of various arseniates of potassium and sodium upon the oxides of the magnesia series, by M. C. Lefèvre.—Note on the volumetric estimation of copper, by MM. A. Etard and P. Lebeau. A method of titration is given by the authors, for which they claim a rapidity and accuracy comparable to the permanganate method for iron; it is based upon the formation of a characteristic violet coloration on the addition of concentrated hydrobromic acid to a solution of the copper salt, and the subsequent decoloration of the solution by standardized stannous chloride solution containing much hydrochloric acid; thus—

$$\underbrace{2CuBr_2 + nHBr}_{\text{Coloured.}} + SnBr_2 = SnBr_4 + \underbrace{Cu_2Br_2 + nHBr.}_{\text{Uncoloured.}}$$

—Preparation of hydroxycamphocarbonic acid from camphocarbonic acid, by MM. A. Haller and Minguin.—Upon the organization of left-handed Prosobranchiate Gastropoda (*Neptunea contraria*, Linnæus), by MM. P. Fischer and E. L. Bouvier.—

Upon the initial cells of the ovary in fresh-water Hydræ, by M. Joannes Chatin.—Note on a new putrefaction ptomaine, obtained by the culture of *Bacterium allii*, by Mr. A. B. Griffiths. The author gives analyses of an alkaloid, produced by the decomposition of albuminoids by this organism, showing it to belong to the hydropyridine series, and to possess the formula of hydrocoridine, $C_{10}H_{17}N$.—On the chromogenous functions of the pyocyanic bacillus, by M. C. Gessard.—Fossil Radiolarians inclosed in albite crystals, by M. A. Issel. The author concludes from the data given—(1) that a sedimentary fossiliferous rock has become crystalline and rich in plagioclastic crystals, without the stratification being sensibly altered; (2) that this change has been produced in a Tertiary formation; (3) that a hydrothermal action is indicated.—A contribution to the history of chrome-iron, by M. Stanislas Meunier.

GERMAN CONTRIBUTIONS TO ETHNOLOGY.

Ethnographische Beiträge zur Kenntniss des Karolinen Archipels. Von J. S. Kubary. 1 Heft, mit 15 Tafeln. (Leyden: P. W. M. Trap, 1889.)

SINCE 1868, when Herr Kubary first entered upon a course of inquiry among the Polynesians, which he had undertaken for the Godeffroy Museum in Hamburg, to which institution he was then officially attached, he has made the archipelago of the Carolines the chief seat and object of his observations. These islands, lying between 5° and 10° N. lat., midway between the Ladrones and New Guinea, and stretching from 138°–160° E. long., have been visited by few white men excepting the traders who occasionally touch there for purposes of barter, or with the object of securing workmen for some more or less remote labour-market on terms of hire which are usually misunderstood by the natives themselves. To this drain on the numbers of able-bodied men, and to continual tribal wars among the different members of the group, the rapid diminution of the population of the Carolines is probably mainly due. In some of the islands the author found that the once numerous families of the kings or chiefs had either wholly died out in recent years, or were only represented by a single male descendant, who, in the absence of any other woman of pure native race, would have to take a half-sister for his wife, if he would avoid the alternative of making a prohibited exogamic marriage.

The probably imminent extermination of these Northern Polynesians gives more than common interest to Herr Kubary's narrative of his long sojourn in the island Yap, and in the Pelew group, or Western Carolines, where he had the good fortune to obtain previously-unknown information regarding the various indigenous moneys in use, and thus to establish the hitherto unsuspected fact that among these people a carefully-adjusted and rigidly-prescribed monetary system has been long in force. Thus in the island of Yap he found that each distinct kind of money could only be used for specially-defined purposes, the form known as *gau*, which consists of strings of equally-sized polished disks of the spondylus, constituting what we may term the gold of the district. This is not current among the general public, but is carefully accumulated by the chiefs, who keep it in reserve to be exchanged with other chiefs for canoes or weapons of all kinds, to be used when they are preparing to make, or to resist, a hostile attack. This spondylus currency has considerable ethnological interest, for we find that the shell can only be procured to the east or the north of Yap, and that it is traditionally the most ancient form of money in use in that and some of the neighbouring islands, while its discovery in old graves of chiefs in the Ladrones seems to point to a common origin of the natives of the latter group and those of the Carolines. Next in value is the *palan*, which consists of round disks of arragonite of various degrees of thickness, which is obtained by the people of Yap at considerable risk and with much labour from certain islands of limestone-formation in the Pelew group. The supply of this money in Yap is mainly dependent on the enterprise of the young men of the villages, who, from time to time combine together to procure a canoe, in which, with the consent of their chief, they repair to the arragonite rocks to extract as much of the stone as their boat will hold. On returning to their native village, they are bound to present their chief with all the larger blocks, after which they dispose of the remainder to the villagers at the rate of the market value of the stone, which is estimated according to its width. Thus, while a fragment measuring an inch or two in diameter is the recognized price of a basket of *taro*, consisting of a definite number of roots, the scale of values rises gradually until it requires a mass six feet in width to purchase a good-sized canoe, or a *gau*-belt adorned with two whale's teeth, which ranks in the eyes of a Yap dandy as the most precious of all personal ornaments. The arrival of a cargo in which there are several of these exceptionally large blocks, is generally soon followed by the breaking out of hostilities between the village chief and his neighbours, as the former seldom loses a chance of making speedy use of these sinews of war; and hence perhaps *palan* is popularly known as "men's money." Next in value to it comes *yar*, which consists of small threaded nacreous shells that serve as small change, and are known as "women's money."

In the Pelew Islands, another form of money, known as *audouth*, is current, whose origin and history are unknown, although the traditions regarding it suggest that it may have been obtained through early trading relations between these islands and remote eastern and western nations. *Audouth* is divided into numerous groups, consisting of coloured or enamelled beads or disks, some of which present a vitreous or earthy character, recalling objects of Chinese or Japanese art; while others, to judge by the coloured illustrations in Herr Kubary's work, are almost identical with the glass beads still largely manufactured in Venice. Each variety of bead has a fixed place on the scale of values, which, beginning from the *taro*-basket unit, gradually rises, until it finally reaches so large an amount that each of the still existing forty or fifty beads, which rank as the highest in the series, and which are all accumulated in the hands of one or two of the kings, actually represents a sum equal to ten or twelve pounds sterling. The extremely limited number of the *audouth*-beads, and the obligation of making payments with only specially prescribed forms of these coins, have led to the establishment of a regularly organized system of loans. By the rules of this system, a man who requires to make a payment in a coin of which he is not possessed, and who has to borrow it from his chief, or some neighbour, is compelled to give in pledge certain definite objects, only redeemable by repayments at fixed periods and rates of interest, while he is, moreover, obliged to refund his debt in the same coin which he originally borrowed.

In his comments on the singular fact that the unclothed, tattooed natives of a remote Polynesian archipelago should possess well-organized systems, based on fixed principles, not only for regulating loans, but also for conducting exchange and barter on equitable terms, Herr Kubary adduces apparently good grounds for assuming that the people have derived these methods,

together with the principal features of their political and social institutions, through their early acquaintance with the higher civilization of the great Malayan States, with whose inhabitants they probably share one common origin. Like these races, the people of the Carolines attach an extraordinary importance to money, which is made the pivot on which everything in the State turns. Thus, the sole penalty for all crimes and misdemeanours is a fixed payment in some definite form of money; and, as among our own northern ancestors, every injury done to man or beast has its recognized price, while every act or event in a man's life from his birth to his death, and beyond it, is charged with a definite payment. Similarly, the favour of the gods in sickness, and the good-will of a chief, would seem to be regarded as only attainable by money offerings to priests or rulers. Strangely enough, however, the chiefs themselves are compelled to make certain prescribed payments in their various transactions with the people, by which means an excessive accumulation of money in the hands of a few is prevented, and a free circulation of the various coins insured; and thus, these uncivilized Polynesians have attempted, after their own fashion, to solve a problem involved in the question of capital and labour.

The author's copiously illustrated descriptions of the dwellings and other buildings erected by the islanders show how closely they approximate in structure and ornamentation to the Malayan type. The arrangements of the interior, however, where the quiet and solitude of the owner of a house are provided for by various portions of the building being tabooed to all strangers, and at certain times to the women and children of the family, afford strong evidence that in their social usages the people have been strongly influenced, probably in recent ages, by intercourse with Polynesians occupying the remoter eastern archipelagoes. This is shown by the uniformity in various practices followed both by the natives of some of the Carolines, and those of other far distant groups.

Nothing, however, is more remarkable than the diversity presented by contiguous islands, for while in the one we find some form of textile art or some method of elaborate tattooing, characteristic of the inhabitants of a far distant archipelago, not a trace of either is to be met with in the neighbouring islands. Even more inexplicable are the differences in stature, appearance, and general physical character among the natives of one island, or one group; and hence it is impossible to arrive at any firmly-based conclusions as to the true ethnic history of the present occupants of the Caroline archipelago.

Herr Kubary has devoted much attention to the study of the various maladies from which the natives suffer, with a view of determining how far these are indigenous or imported; and, while he highly commends the patience under suffering of these gentle, unsophisticated natives, he shows that various specific forms of disease, which are usually malignant among civilized communities, here present a benign character. His remarks on this subject are full of interest, as are also his descriptions of the various local remedies employed, among which it would appear that some possess such well-marked specific properties as to merit the careful attention of our own pharmacologists.

The present volume, which is to be followed by a further series of Herr Kubary's contributions, is edited by Dr. Schmeltz, on behalf of the directors of the Imperial Museum of Ethnology in Berlin, where the most valuable of the author's collections are deposited.

ENGLISH AND SCOTTISH RAILWAYS.

The Railways of England. By W. M. Acworth. Second Edition. (London: John Murray, 1889.)

The Railways of Scotland. By W. M. Acworth. (London: John Murray, 1890.)

BEYOND the comparatively small railway circle, there are many persons who take great interest in the railway system of this country. Any particularly fast train is carefully noted, and compared detail for detail with its predecessor; and its particular virtues are pointed out. To such persons the works before us will be most welcome. To railway men we need only say that not to read these books will be a great loss and a mistake. Mr. Acworth has evidently had excellent opportunities for observation, and he has not failed to make good use of the chances thus obtained for careful study of the many different phases of railway life. The author confesses to have written anonymously not a few criticisms on the management of certain English railways, which were meant to be particularly scathing. In the present books we can find nothing of the kind; in fact, in most cases the author uses language of almost unvarying panegyric, even the hunting-ground of the "Flying Watkin Express" coming in for nothing but praise. This is certainly as it should be, for those who know anything of the subject are aware that the English railway system taken as a whole is second to none in the world, either in management, rolling-stock, or permanent way.

The volume on the railways of England deals principally with the railways terminating in London. An historical sketch of the early railways is given, and we find, besides much useful matter, many amusing anecdotes. The author deals at length with the change wrought by the introduction of railways in the various trades affected by the withdrawal of the stage-coach, and the consequent loss of trade to many towns and villages on the old turnpike roads, as well as the birth of new trades and occupations caused by the advance of the railway system.

The London and North-Western Railway is the first one noticed, in Chapter II. The territory of this railway extends from London in the south to Carlisle in the north, and from Cambridge in the east to Swansea and Holyhead in the west. The description naturally begins at Crewe, for at this station are the main locomotive and other works of the Company, employing about 6000 men. Here also are the head-quarters of the locomotive staff, under Mr. F. W. Webb, the able mechanical superintendent. The author gives an excellent description of the works, and the many special manufactures carried on. The illustration of the Webb transverse steel sleeper shows how a steel sleeper can be designed to suit the English mongrel-sectioned rail known as the "Bullhead." It is a pity some enterprising railway manager in England does not give the Indian all-steel permanent way a trial,

viz. a Vignoles or flanged rail with a transverse steel sleeper formed out of a ribbed plate, with lugs or clips formed out of the solid to take the rail flange, and fastened with a steel key. In this system there is nothing that can get loose, and excellent results are obtained in India, where several millions are now in use.

In Chapter IV. we find the Midland Railway thoroughly discussed. The growth of this enterprising and pushing Company is carefully and vividly delineated. This large system, like most others, is the result of the amalgamation of many small companies, and, under an enlightened management, it has long been considered the most progressive railway in this country. The author gives a capital description of this large system, and many interesting statistics. Among the many special details, perhaps the Lickey incline on the Birmingham and Gloucester section is of most interest. On this incline, having a gradient of 1 in 37, the traffic has always been worked by locomotives, even in the days when stationary engines were used to haul the trains out of Euston Station and Lime Street Station at Liverpool; and further, in these early days (1839), the English-built locomotive was unable to be of much use on this incline, and some American locomotives were imported and succeeded in working the traffic. Derby is the "Crewe" of the Midland. Here the Company builds the locomotives, carriages, and most of the waggons. The travelling public owe much to the Midland Company. On this line the author tells us most of the new departures in rolling-stock and details were originally tried, the Pullman car and many other equally important novelties, down to the diminutive but most useful apparatus, the sand-blast, for sanding the rails under the treads of the driving-wheels of the locomotive. The effects of this apparatus are very interesting, and its use is becoming universal. So much does it add to the effectiveness of a single-wheeled locomotive that it is possible to use it on trains in place of the four-coupled engine, a saving evident to those familiar with the subject. The single-wheeled engines, running at high speeds, are more free; which means less wear and tear to the engine itself, and probably the permanent way. With an express train the sand-blast apparatus uses about nine ounces of sand per mile, giving a continuous supply to the driving-wheels; and, be the rails ever so greasy, the wheels seldom slip half a turn. The testing of the materials used at Derby Works appears to be very efficient; the steel, particularly for plates, axles, tyres, &c., being thoroughly tested by tensile and bending tests, and by chemical analysis.

Chapter V. deals with the Great Northern, North-Eastern, and Manchester, Sheffield, and Lincolnshire Railways. In any description of the Great Northern system it would be impossible to pass over the splendid running of the Company's express trains. Some of these are, without doubt, the fastest in the world. The 105¼ miles between Grantham and London are continuously "done" in 117 minutes, or at the rate of 54 miles per hour; and both up and down trains are known to get over 60 consecutive miles in as many minutes. On one occasion, the author states, the 105¼ miles were "reeled off" in 112 minutes—a result worthy of Mr. Stirling's splendid locomotives. The description of driving the "Flying Scot" is very true, and we are glad to observe that the author combats the nonsense written to the daily press concerning the drivers and firemen of the Scotch expresses "being paralyzed with fear at the awful speeds." No two men are prouder of their positions, nor would they exchange into any other link. Their position is, in fact, the blue ribbon of the foot-plate.

In dealing with the North-Eastern Railway, the author gives much useful information on the subject of the compound locomotive. The locomotive superintendent of that railway, Mr. T. W. Worsdell, uses probably the best arrangement of cylinders, &c., possible to fulfil the many conditions under which a satisfactory locomotive must be constructed, and the results obtained appear to point to a great saving in fuel. We would commend to our readers the description of the snow-block on this railway in the year 1886; it is well written.

With reference to the electric lighting of trains on the Glasgow underground section of the North British Railway, it should be noted that the current is taken off the third insulated rail, not by a brush, as stated by the author, but by means of a wheel in a swing frame under each coach. This wheel runs on the central elevated and insulated rail, and each coach is electrically independent of any other. The system appears to work very well. To the Manchester, Sheffield, and Lincolnshire Railway the author gives little attention, for reasons stated on p. 193. Probably no line in this country is more handicapped by heavy gradients on its main line, and the locomotive stock has had to be designed to satisfy the conditions, more especially on the section between Manchester and Sheffield. The late Mr. Charles Sacré, the eminent engineer and locomotive superintendent of that railway, designed some particularly fine four-coupled bogie engines for the passenger service, and his goods engines did good work on the heavy sections.

The Great Western Railway loses nothing by the description given in Chapter VI. This historical line is well described, and the "battle of the gauges" thoroughly gone into. It is to be regretted that some compromise was not made between the rival gauges; for it is now evident that the four feet eight and a half inches gauge—the standard one in this country—is not wide enough. Locomotives and rolling stock have grown so much that locomotive engineers are in difficulties when trying to design more powerful engines. Take, for instance, the Indian or the Irish broad gauge; in these cases the engines are not limited in width so much, and can have ample bearing surfaces; as well as, for inside cylinder engines, crank axles not tied down by considerations of cylinder centres and the like. A ride on the "Dutchman" express locomotive is well enough described to make many young locomotive engineers long to have shared with the author that thoroughly enjoyable experience. The Severn Tunnel is well treated in this chapter. Chapter VII. deals with the South-Western Railway, and the following one gives much useful information of that model of all southern railways—the London, Brighton, and South Coast Railway. In noticing the latter we cannot but express our regret for the loss that Company and locomotive engineering generally have sustained by the recent death of Mr. William Stroudley. Without doubt one of our ablest railway engineers, he brought the designing of locomotives and

rolling-stock to the highest pitch; his engines are patterns to be used with advantage, and their coal consumption is the lowest on record. Chapter IX. describes the South-Eastern and Chatham Railways; and the volume concludes with Chapter X., on the Great Eastern Railway. These last chapters lack none of the interest to be found in the earlier ones in the book.

The second volume, on Scottish railways, is merely a continuation of the first, and is written in the same lucid style. Its most interesting part is a description of the Forth Bridge. Mr. Acworth gives a good account of the bridge and the earlier schemes proposed for crossing the Forth.

Mr. Acworth has written two most interesting books, which will be of great use to all in any way connected with, or interested in, the British railway system.

N. J. L.

DISEASES OF PLANTS.

Diseases of Plants. By Prof. H. Marshall Ward, F.R.S., M.A. (London: Society for Promoting Christian Knowledge.)

THIS little book is an excellent popular introduction to the study of the diseases of plants, in so far as they are due to the attacks of parasitic Fungi or similar organisms. The author, who has made this field of research especially his own, succeeds in being intelligible and interesting to ordinary readers, without in any degree sacrificing the scientific character of his work.

The book is illustrated by fifty-three woodcuts, which have been very well selected, many of them from the author's own papers. In certain cases, however, the engraving leaves something to be desired, and scarcely does justice to the original figures.

An introductory chapter explains what is here meant by disease in plants, namely "those disturbances of the structure and functions of the plant, which actually threaten the life of the plants, or at least their existence as useful objects of culture." The two factors of disease, the external cause on the one hand, and the condition of the patient on the other, are clearly distinguished.

The second chapter gives a general account of Fungi as saprophytes and parasites. Mucor is described as an example of the former, and vine-mildew (*Peronospora viticola*) of the latter group.

The succeeding nine chapters, forming the bulk of the book, are occupied with the consideration of special diseases.

First comes the "damping-off" of seedlings, a disease only too well known to gardeners, due to the attacks of various species of Pythium. The whole life-history of the parasite is described. In Fig. 9 it is a pity that the point of attachment of the antheridium is not more clearly shown.

Next, we have an account of the very interesting disease of cabbages and other Crucifers, known as "fingers and toes," "club-root," &c. Here the cause of the mischief is a Myxomycete, and this is the only case of a non-fungoid disease described in the book. Happily, a satisfactory cure can here be prescribed.

Chap. v. is on the potato-disease. An account of the normal mode of nutrition of the plant in health is introduced in order to show the exact nature of the deadly injury which is wrought by the Phytophthora. As a preventive measure, the selection of resistant varieties of the potato is especially recommended. Chap. vi. is devoted to the "smut" of corn. The cause of the frequent failure of protective dressings applied to the ripe grain is discussed. If, however, as Jensen believes, the ovule may be infected at the time of flowering, an altogether new light is thrown on this question.

After a chapter on the disease known as "bladder-plums," caused by the yeast-like Fungus Exoascus, we come to the lily-disease. The Fungus which is here responsible has been shown by Prof. Ward to afford an excellent example of a saprophyte which can become a parasite on occasion.

The next three chapters describe the ergot of rye, the mildew of hop (Podosphæra), and the rust of wheat. In the case of the hop-disease, a figure of the conidia might have been added with advantage. The now familiar but always interesting story of the heterœcism of rust is well told.

With a caution which in the case of a popular work cannot be too highly commended, the author avoids expressing any opinion on the subjects of fertilization in Podosphæra, and of the function of the spermogonia in Æcidium.

In the concluding chapter, Prof. Ward endeavours to interest his readers in the wider questions of mycology, so fascinating to the botanist, such as the phylogenetic origin and relationships of the Fungi.

The book should have a wide circulation among the numerous classes interested in the important group of diseases of plants with which it deals.

D. H. S.

OUR BOOK SHELF.

The Physician as Naturalist. Addresses and Memoirs bearing on the History of and Progress of Medicine chiefly during the last hundred years. By W. T. Gairdner, M.D. (Glasgow: Maclehose and Sons, 1889.)

A SUCCESSFUL physician, during a long and busy life, is frequently called upon to preside and deliver addresses at meetings at which he is expected to treat his subjects in a more or less popular manner.

Dr. Gairdner has brought together a most interesting series of such addresses, which fall into two main groups. First, those in which he has contrasted the treatment of the present day with that in vogue among our predecessors of more or less remote times; and in which he has attempted to present the answer to that ever-interesting question, "Is the treatment of disease adopted at the present day superior to that in vogue formerly? And if so, in what does its superiority consist?" Second, those in which he lays down the lines on which he considers the medical education of the future should be conducted, in order to lead to still greater advances.

The dependence of modern treatment upon the discussion of accumulations of facts, and not solely upon theory, and the necessity of making experience and

not authority the arbiter in cases of doubt, are the conclusions which the author inculcates throughout.

A century ago it was considered a fundamental principle that venesection was essential in most, if not all, serious illnesses; and, to such an extent was this carried, that 200 ounces of blood were sometimes drawn off during a week, and even half that amount in 24 hours. Next came a reaction, and the theory that fever patients required stimulation, rather than venesection, led to the administration of enormous quantities of alcohol, especially at the hands of Dr. Todd, who at times administered more than four gallons of brandy to young girls during an illness. Finally, to Dr. Gairdner himself is due much of the credit of the modern treatment; for in 1864 he showed that in fevers, especially typhus, the mortality is far less when the patients are supported with milk and not with alcohol. Quackery and humbug meet with but little mercy at the author's hands, and the hollowness of the pretensions of homœopathy is well brought out in an essay contributed thirty years ago, which is reprinted in this collection.

The volume should meet with a large circle of readers outside the medical profession, as it is eminently readable and touches upon many points in the past history of medicine as well as in modern practice, which are of interest to all.

Materials for a Flora of the Malayan Peninsula. Part I. By Dr. George King, F.R.S., Calcutta. Pp. 50. (Reprinted from the *Journal of the Asiatic Society of Bengal*, 1889, No. 4.)

Sir J. D. Hooker's "Flora of British India," of which five volumes out of seven are now printed, marks an era in tropical botany, inasmuch as it will probably contain descriptions, with their synonymy, of half the tropical plants of the Old World. It furnishes, therefore, a broad platform for his successors to build upon. It is not likely that within the bounds of India proper many new plants still remain to be described; but it is not so in the wonderfully rich flora of the Malay peninsula. During the last ten years large collections have been accumulated at Calcutta from this region, gathered mainly by Scortechini and other collectors who have been sent out by the authorities of the Calcutta Botanic Garden. In the present pamphlet, which is reprinted from the Journal of the Asiatic Society of Bengal, Dr. King, the Director of the Calcutta Garden, begins a synopsis of the plants which are indigenous to the British provinces of the Malay peninsula, including the islands of Singapore, Penang, and the Nicobar and Andaman groups.

In this present paper he deals with the orders Ranunculaceæ, Dilleniaceæ, Magnoliaceæ, Menispermaceæ, Nymphæaceæ, Capparideæ, and Violaceæ, leaving over the intricate and largely represented order Anonaceæ for another time. In these seven orders there are 35 Malayan genera and 90 species, of which 32 are here described for the first time. Amongst the novelties are included a Magnolia, a Manglietia, 3 Talaumas, an Illicium, 4 species of Capparis, and no less then 11 new Alsodeias. Besides the species here described for the first time, there are several others, known previously in Java and China, which are new to British India. It will be seen that the work will add materially to our knowledge of Indian plants, and it is to be hoped that Dr. King, in the midst of his multifarious official duties, may be able to go on with it quickly and steadily. It is hardly worth while, we think, in a series of papers of this kind, to take up space and time by recapitulating in detail the characters of the orders and genera, as, from the nature of the case, it is essentially a supplement to Hooker's "Flora of British India," in which they are already fully worked out.

Panmixia.

Seeing that the whole structure of Prof. Weismann's theory is founded—both logically and historically—upon the doctrine of "panmixia," and seeing that in some important respects his statement of the doctrine appears to me demonstrably erroneous, I propose to supply a paper on the subject.

It will be remembered that the principal evidence on which Mr. Darwin relied to prove the inheritance of acquired characters was that which he derived from the apparently inherited effects of use and disuse—especially as regards the bones of our domesticated animals when compared with the corresponding bones of ancestral stocks in a state of nature. Now, in all his investigations regarding this matter, the increase or decrease of a part was estimated, not by directly comparing, say, the wing bones of a domesticated duck with the wing-bones of a wild duck, but by comparing the *ratio* between the wing and leg bones of a tame duck with the *ratio* between the wing and leg bones of a wild duck. Consequently, if there be any reason to doubt the supposition that a really inherited diminution of a part thus estimated is due to the inherited effects of diminished use, such a doubt will also require to extend to the evidence of a really inherited augmentation of a part being due to the inherited effects of augmented use. Now, there is the gravest possible doubt lying against the supposition that any really inherited decrease is due to the inherited effects of disuse. For it may be—and, at any rate to a large extent, must be—due to another principle which it is remarkably strange that Mr. Darwin should have overlooked. This is the principle of what Prof. Weismann has called panmixia. If any structure which was originally built up by natural selection on account of its use, ceases any longer to be of so much use, in whatever degree it so ceases to be of use, in that degree will the premium before set upon it by natural selection be withdrawn. And the consequence of this withdrawal of selection as regards that particular part will be to allow the part in a corresponding measure to degenerate through successive generations. Weismann calls this principle panmixia, because, by such withdrawal of natural selection from any particular part, promiscuous breeding ensues with regard to that part. And it is easy to see that this principle must be one of great importance in nature, inasmuch as it must necessarily come into operation in all cases where a structure or an instinct has ceased to be useful. It is likewise easy to see that its effects —viz. of inducing degeneration—must be precisely the same as those which were attributed by Mr. Darwin to the inherited effects of disuse; and, therefore, that most of the evidence on which he relied to prove the inherited effects both of use and of disuse is vitiated by the fact that the idea of panmixia never happened to occur to him. In this connection, however, it requires to be stated that the idea first of all occurred to myself, unfortunately just after the appearance of his last edition of the "Origin of Species." I then published in these columns a somewhat detailed exposition of the subject (see NATURE, vol. ix. pp. 361, 440, vol. x. p. 164). I called the principle the cessation of selection—which still seems to me a better, because a more descriptive, term than panmixia—and at first it appeared to me, as it now appears to Weismann, entirely to supersede the necessity of supposing that the effects of use and of disuse are ever inherited in any degree at all. Thus it obviously raised the whole question touching the admissibility of the Lamarckian principles in any case, or the question which is now being so much discussed concerning the possible inheritance of acquired as distinguished from congenital characters. But Mr. Darwin satisfied me that this larger question could not be raised. That is to say, although he fully accepted the principle of panmixia, and as fully acknowledged its obvious importance, he left no doubt in my mind that there was independent evidence for the transmission of acquired characters sufficient in amount to leave the general structure of his previous theory unaffected by what he nevertheless recognized as a necessarily additional factor in it. And forasmuch as no further facts bearing upon the subject have been forthcoming since that time, I see no reason to change the judgment that was then formed.

There is, however, one respect in which Prof. Weismann's statement of the principle of panmixia differs from that which was considered by Mr. Darwin; and it is this difference of statement—which amounts to an important difference of theory—that I now wish to discuss.

The difference in question is, that while Prof. Weismann believes the cessation of selection to be capable of inducing degeneration down to the almost complete disappearance of a rudimentary organ, I have argued that, *unless assisted by some other principle*, it can at most only reduce the degenerating organ to considerably above one-half its original size—or probably not through so much as one-quarter. The ground of this argument (which is given in detail in the NATURE articles before alluded to) is, that panmixia depends for its action upon fortuitous variations round an ever-diminishing average—the average thus diminishing because it is no longer *sustained* by natural selection. But although no longer sustained by *natural selection*, it does continue to be sustained by *heredity*; and therefore, as long as the force of heredity persists unimpaired, fortuitous variations alone—or variation which is no longer controlled by natural selection—cannot reduce the dwindling organ to so much as one-half of its original size; indeed, as above foreshadowed, the balance between the positive force of heredity and the negative effects of promiscuous variability will probably be arrived at considerably above the middle line thus indicated. Only if for any reason the force of heredity begins to fail, can the average round which the cessation of selection works become a progressively diminishing average. In other words, so long as the original force of heredity as regards the useless organ remains unimpaired, the mere withdrawal of selection cannot reduce the organ much below the level of efficiency above which it was previously *maintained* by the *presence* of selection. If we take this level to be 70 per cent. of the original size, cessation of selection will reduce the organ through the 30 per cent., and there leave it fluctuating about this average, unless for any reason the force of heredity begins to fail—in which case, of course, the average will progressively fall in proportion to the progressive weakening of this force.

Now, according to my views, the force of heredity under such circumstances is always bound to fail, and this for two reasons. In the first place, it must usually happen that when an organ becomes useless, natural selection as regards that organ will not only *cease*, but become *reversed*. For the organ is now absorbing nutriment, causing weight, occupying space, and so on, *uselessly*. Hence, even if it be not also a source of actual danger, "economy of growth" will determine a reversal of selection against an organ which is now not merely useless, but deleterious. And this degenerating influence of the reversal of selection will throughout be assisted by the cessation of selection, which will now be always acting round a continuously sinking average. Nevertheless, a point of balance will eventually be reached in this case, just as it was in the previous case where the cessation of selection was supposed to be working alone. For, where the reversal of selection has reduced the diminishing organ to so minute a size that its presence is no longer a source of detriment to the organism, the cessation of selection will carry the reduction a small degree further; and then the organ will remain as a "rudiment." And so it will remain permanently, unless there be some further reason why the still remaining force of heredity should be abolished. This further reason I found in the consideration that, however enduring we may suppose the force of heredity to be, it would be unreasonable to suppose that it is actually everlasting; and, therefore, that we may reasonably attribute the eventual disappearance of rudimentary organs to the eventual failure of heredity itself. In support of this view there is the fact that rudimentary organs, although very persistent, are not everlasting. That they should be very persistent is what we should expect, if the hold which heredity has upon them is great in proportion to the time during which they were originally useful, and so firmly stamped upon the organization by natural selection causing them to be strongly inherited in the first instance. Thus, for example, we might expect that it would be more difficult finally to eradicate the rudiment of a wing than the rudiment of a feather; and accordingly we find it a general rule that long-enduring rudiments are rudiments of organs distinctive of the higher taxonomic divisions—*i.e.* of organs which were longest in building up in the first place, and longest sustained in a state of working efficiency in the second place. Again, that rudimentary organs, although in such cases very persistent, should not be everlasting, is also what we should expect, unless (like Weismann) we have some argumentative reason to sustain the doctrine that the force of heredity is inexhaustible, so that never in any case can it become enfeebled by a mere lapse of time—a doctrine the validity of which in the present connection I will consider later on.

Thus, upon the whole, my view of the facts of degeneration remains the same as it was when first published in these columns sixteen years ago, and may be summarized as follows.

The cessation of selection when working alone (as it probably does work in our domesticated animals, and during the first centuries of its working upon structures or colours which do not entail any danger to, or perceptible drain upon the nutritive resources of, the organism) cannot cause degeneration below, probably, some 20 to 30 per cent. But if from the first the cessation of selection has been assisted by the *reversal* of selection (on account of the degenerating structure having originally been of a size sufficient to entail a perceptible drain on the nutritive resources of the organism, having now become a source of danger, and so forth), the two principles acting together will continue to reduce the ever-diminishing structure down to the point at which its presence is no longer a perceptible disadvantage to the species. When that point is reached, the reversal of selection will terminate, and the cessation of selection will not then be able of itself to reduce the organ through more than at most a very few further percentages of its original size. But, after this point has been reached, the now total absence of selection, either for or against the organ, will sooner or later entail this further and most important consequence—viz. a failure of heredity as regards the organ. So long as the organ was of use, its efficiency was constantly *maintained* by the *presence* of selection—which is merely another way of saying that selection was constantly maintaining the force of heredity as regards that organ. But as soon as the organ ceased to be of use, selection ceased to maintain the force of heredity; and thus, sooner or later, that force began to waver or fade. Now it is this wavering or fading of the force of heredity, thus originally due to the cessation of selection, that in turn *co-operates* with the still continued cessation of selection (panmixia) in reducing the structure below the level where its reduction was left by the actual reversal of selection. So that from that level downwards the cessation of selection and the consequent failing of heredity act and react in their common work of causing obsolescence. In the case of newly acquired characters the force of heredity will be less than in that of more anciently acquired characters; and thus we can understand the long endurance of "vestiges" characteristic of the higher taxonomic divisions, as compared with those characteristic of the lower. But in all cases, if time enough be allowed, under the cessation of selection the force of heredity will eventually fall to zero, when the hitherto obsolescent structure will finally become obsolete.[1]

Let us now turn to Weismann's view of degeneration. First of all, he has omitted to perceive that "panmixia" alone (if unassisted either by reversed selection or an inherent diminishing of the force of heredity) cannot reduce a functionless organ to the condition of a *rudiment*. Therefore he everywhere represents panmixia (or the mere *cessation* of selection) as of itself sufficient to cause degeneration, say from 100 to 5, instead of from 100 to 80 or 70, which, for the reasons above given, appeared (and still appears) to me about the most that this principle alone can accomplish, so long as the original force of heredity continues unimpaired. No doubt we have here what must be regarded as a mere oversight on the part of Prof. Weismann; but the oversight is rendered remarkable by the fact that he *does* invoke the aid of reversed selection *in order to explain the final disappearance of a rudiment*. Yet it is self-evident that the reversal of selection must be much more active during the initial than during the final stages of degeneration, seeing that, *ex hypothesi*, the greater the degree of reduction which has been attained the less must be the detriment arising from any useless expenditure of nutrition, &c.

And this leads me to a second oversight in Prof. Weismann's statement, which is of more importance than the first. For the

[1] It may not be needless to add that in the case of newly acquired and comparatively trivial characters, with regard to which reversal of selection is not likely to take place (*e.g.* slight differences of colour between allied species), cessation of selection is likely to be very soon assisted by a failure in the force of heredity; seeing that such newly acquired characters will not be so strongly inherited as are the more ancient characters distinctive of higher taxonomic groups.

place at which he does invoke the assistance of reversed selection is exactly the place at which reversed selection must necessarily have ceased to act. This place, as already explained, is where an obsolescent organ has become rudimentary, or, as above supposed, reduced to 5 per cent. of its original size; and the reason why he invokes the aid of reversed selection at this place is in order to save his doctrine of "the stability of germ-plasm." That the force of heredity should finally become exhausted if no longer *maintained* by the *presence* of selection, is what Darwin's theory of perishable gemmules would expect to be the case, while such a fact would be fatal to Weismann's theory of an imperishable germ-plasm. Therefore he seeks to explain the eventual failure of heredity (which is certainly a fact) by supposing that after the point at which the cessation of selection alone can no longer act (and which his first oversight has placed some 70 per cent. too low), the reversal of selection will begin to act directly against the force of heredity as regards the diminishing organ, until such direct action of reversed selection will have removed the organ altogether. Or, in his own words, "The complete disappearance of a rudimentary organ can only take place by the operation of natural selection; this principle will lead to its diminution, inasmuch as the disappearing structure takes the place and the nutriment of other useful and important organs." That is to say, the rudimentary organ finally disappears, not because the force of heredity is finally exhausted, but because natural selection has begun to utilize this force against the continuance of the organ—always picking out those congenital variations of the organ which are of smallest size, and thus, by its now *reversed* action, *reversing* the force of heredity as regards the organ.

Now, the oversight here is that the smaller the disappearing structure becomes, the less hold must "this principle" of reversed selection retain upon it. As above observed, during the earlier stages of reduction (or while co-operating with the cessation of selection) the reversal of selection will be at its *maximum* of efficiency; but, as the process of diminution continues, a point must eventually be reached at which the reversal of selection can no longer act. Take the original mass of a now obsolescent organ in relation to that of the entire organism of which it then formed a part to be represented by the ratio 1 : 100. For the sake of argument we may assume that the mass of the organism has throughout remained constant, and that by "mass" in both cases is meant capacity for absorbing nutriment, causing weight, occupying space, and so forth. Now, we may further assume that when the mass of the organ stood to that of its organism in the ratio of 1 : 100, natural selection was strongly reversed with respect to the organ. But when this ratio fell to 1 : 1000, the activity of such reversal must have become enormously diminished, even if it still continued to exercise any influence at all. For we must remember, on the one hand, that the reversal of selection can only act so long as the presence of a diminishing organ continues to be so injurious that variations in its size are matters of life and death in the struggle for existence; and, on the other hand, that natural selection in the case of the diminishing organ does not have reference to the presence and the absence of the organ, but only to such variations in its mass as any given generation may supply. Now, the process of reduction does not end even at 1 : 1000. It goes on to 1 : 10,000, and eventually 1 : ∞. Consequently, however great our faith in natural selection may be, a point must eventually come for all of us at which we can no longer believe that the reduction of an obsolescent organ is due to this cause. And I cannot doubt that if Prof. Weismann had sufficiently considered the matter, he would not have committed himself to the statement that "the complete disappearance of a rudimentary organ can only take place by the operation of natural selection."

According to my view of the matter, the complete disappearance of a rudimentary organ can only take place by the *cessation* of natural selection, which permits the eventual exhaustion of heredity, when heredity is thus simply left to itself. During all the earlier stages of reduction, the cessation of positive selection was assisted in its work by the activity of negative or reversed selection; but when the rudiment became too small for such assistance any longer to be supplied, the rudiment persisted in that greatly reduced condition until the force of heredity with regard to it was eventually worn out. This appears to me, as it appeared to me in 1874, the only reasonable conclusion that can be drawn from the facts. And it is because this conclusion is fatal to Prof. Weismann's doctrine of the permanent "stability" of germ-plasm, while quite in accordance with all theories which belong to the family of pangenesis, that I deem the facts of degeneration of great importance as tests between these rival interpretations of the facts of heredity. It is on this account that I have occupied so much space with the foregoing discussion; and I shall be glad to ascertain whether any of the followers of Prof. Weismann are able to controvert the views which I have thus re-published.

London, February 4. GEORGE J. ROMANES.

P.S.—Since the above article was sent in, Prof. Weismann has published in these columns (February 6) his reply to a criticism by Prof. Vines (October 24, 1889). In this reply he appears to have considerably modified his views on the theory of degeneration; for while in his essays he says (as in the passage above quoted) that "the complete disappearance of a rudimentary organ can only take place by the operation of natural selection"—*i.e.* only by the *reversal* of selection,—in his reply to Prof. Vines he says, "I believe that I have proved that organs no longer in use become rudimentary, and must finally disappear, solely by 'panmixia'; not through the direct action of disuse, but because natural selection no longer sustains their standard structure"—*i.e.* solely by the *cessation* of selection. Obviously, there is here a flat contradiction. If Prof. Weismann now believes that a rudimentary organ "must finally disappear *solely*" through the *withdrawal* of selection, he has abandoned his previous belief that "the complete disappearance of a rudimentary organ can *only* take place by the *operation* of selection." And this change of belief on his part is a matter of the highest importance to his system of theories as a whole, since it betokens a surrender of his doctrine of the "stability" of germ-plasm—or of the virtually everlasting persistence of the force of heredity, and the consequent necessity for a reversal of this force itself (by natural selection placing its premium on *minus* instead of on *plus* variations) in order that a rudimentary organ should finally disappear. In other words, it now seems he no longer believes that the force of heredity in one direction (that of sustaining a rudimentary organ) can only be abolished by the active influence of natural selection determining this force in the opposite direction (that of removing a rudimentary organ). It seems he now believes that the force of heredity, if merely left to itself by the withdrawal of natural selection altogether, will sooner or later become exhausted through the mere lapse of time. This, of course, is in all respects my own theory of the matter as originally published in these columns; but I do not see how it is to be reconciled with Prof. Weismann's doctrine of so high a degree of stability on the part of germ-plasm, that we must look to the Protozoa and the Protophyta for the original source of congenital variations as now exhibited by the Metazoa and Metaphyta. Nevertheless, and so far as the philosophy of degeneration is concerned, I shall be very glad if (as it now appears) Prof. Weismann's more recent contemplation has brought his principle of panmixia into exact coincidence with that of my cessation of selection.—G. J. R.

Newton in Perspective.

THE interesting modern science termed by the Germans *Geometrie der Lage*, and by the French and other Latin peoples *géométrie de position*, may be traced in germ to that part of Newton's "Principia" which deals with the construction of curves of the second order, and to what has survived in tradition of Pascal's lost manuscript entitled "Traité complet des Coniques." The more recent developments of this important subject cast much new light upon Newton's propositions, many of which we are now enabled to solve by easier and more direct methods. A noteworthy example is here fully worked out, in order to show how problems which Newton solved by indirect and circuitous processes may be solved more simply by the aid of modern graphics.

PROBLEM.—*Given the four tangents EA, AB, BC', C'D (Fig. 1), as well as a point of contact; to construct the conic.*—First it will be necessary to give some faint idea of Newton's solution of this problem, without entering upon details which can be found in the Latin edition of the "Principia" edited by Sir William Thomson and Prof. H. Blackburn. Having expounded at great length a general theorem for the transformation of curves, Newton transforms the quadrilateral figure formed by the four tangents into a parallelogram. Then he joins the given point of contact *y*, transformed according to the same principle as the given four tangents, to the centre O of the parallelogram

—which is also the centre of the conic—and producing the line yO to y', so that Oy' may be equal to Oy, he determines a second point of contact y' on the conic, by which means the problem is reduced to the case dealt with in the preceding proposition, showing how to construct the curve when three tangents and two points are given. Having in this way found five points on the transformed conic, Newton next proceeds to retransform the whole of the figure to its original shape, in order to apply his well-known method of constructing a conic of which five points are known.

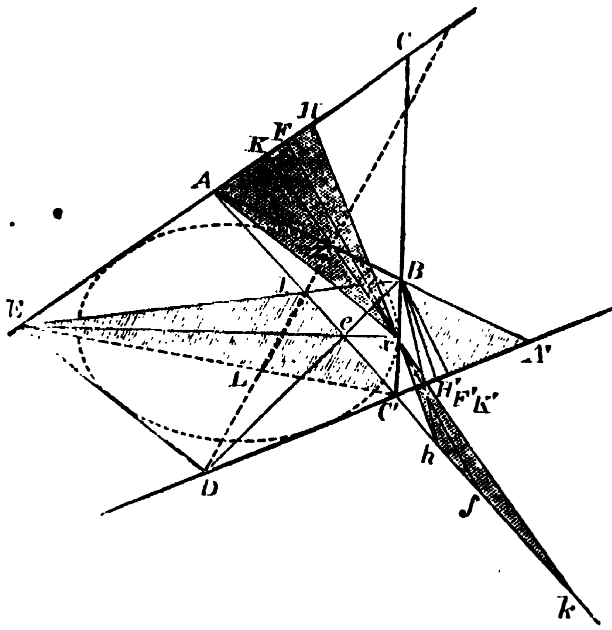

FIG. 1.

Now all these transformations and retransformations of lines and quadrangles involve very tedious and laborious operations, which can be avoided by borrowing a few simple principles of modern geometry. The following two original solutions of the above problem will serve to illustrate this statement.

SOLUTION.—*Case* I. *When the given point of contact x lies on one of the given four tangents.*—Assume the given point of contact x and the neighbouring apex B of the quadrangle as centres of projection, and the given tangent lines EA and C′D as punctuated lines. The meaning of the term "punctuated line," familiar to students of modern geometry, will appear in the sequel.

It will be seen that the fourth tangent AB cuts the first punctuated line EA in A and the second punctuated line C′D in A′. Now, according to a proposition of modern geometry, if the points A and A′, in which the tangent AB intersects the two punctuated tangents EA and C′D, be projected by rays xA and BA′ issuing from their respective centres of projection x and B, those rays will meet in a point A, situate on what is termed the perspective line of the pencils x and B.

Next imagine the tangent AB to revolve upon the curve so as gradually to approach the limiting position BC. In that case A will approach C, B will fall upon C′, and the intersection of the projecting rays xC and BC′ will coincide with C′, which is therefore a second point on AC′, the required perspective line of the pencils x and B. Wherefore, in order to find a fifth or any number of tangents to the curve, choose any point E on the punctuated line EA, and project this point from x, the corresponding centre of projection, upon the perspective line AC′ in e; and then project e from the second centre of projection B upon the corresponding punctuated line C′D in D. The line ED is a fifth tangent to the conic, and any number of tangents can be drawn in precisely the same way. Then, let F be any other point on EA. Join and produce Fx, intersecting the perspective line AC′ in f; and from the centre B project f upon the punctuated tangent C′D in F′. Then the line FF′ will be a sixth tangent to the conic.

COR. I.—Since the lines AC′, BD, and xE all meet in the same point e, it follows that, in any pentagon ABC′DE circumscribed to a conic, the opposite diagonals AC′ and BD and the line joining the fifth point E to the opposite point of contact x all meet in the same point.

Case II. *When the given point of contact z lies outside of the four tangents AEDC′B.*—By the corollary, Case I., if AB be the fifth tangent, it must pass through the given point of contact z in such a direction that the diagonals C′A and EB may intersect in a point I situate on a given line Dz.

Now let AB revolve about the fixed point of contact z as a fulcrum, whilst A and B describe the lines EC and CC′ (Figs. 1 and 2). Then, necessarily, z will be the centre of perspectivity of the punctuated lines EC and CC′, whose centres of projection are respectively C′ and E. But, by a well-known proposition of geometry of position, when the points of two converging punctuated lines, such as EC and CC′, are projected from opposite centres in this fashion, the locus of the successive intersections of the rays C′A and EB, or in other words the variable position of the point I, will describe a conic, which in the present instance is a hyperbola. But the problem is how to find the point I on the transversal Lz without constructing the hyperbola, four points on which are already known. For it will be observed that, when A coincides with E, the point B will lie on the prolongation of Ez, and the corresponding projecting rays Ez and C′E will meet in E, a point on the hyperbola. Similarly C′ is a second point on the hyperbola. Again, as AB continues to revolve about the fixed centre of perspectivity z, its intersections A and B with the punctuated lines EC and CC′ will ultimately coalesce in the point C, common to both those lines. Hence, since in that case the rays projecting the double point C from the centres E and C′ meet in C, this point must lie on the hyperbola.

Fourthly, if the line Cz be produced to intersect the line EC′ in N, it can be easily shown that i, the third point in the harmonic ratio CziN, is a fourth point on the hyperbola. A fifth point can be found by simply drawing AB in any direction traversing z and intersecting EC in A′ and CC′ in B′, and then projecting A′ and B′ from the centres C′ and E respectively by rays C′A′ and EB′ which will meet in a fifth point upon the hyperbola.

Thus, given these or in fact any five points EDiTH (Fig. 2)

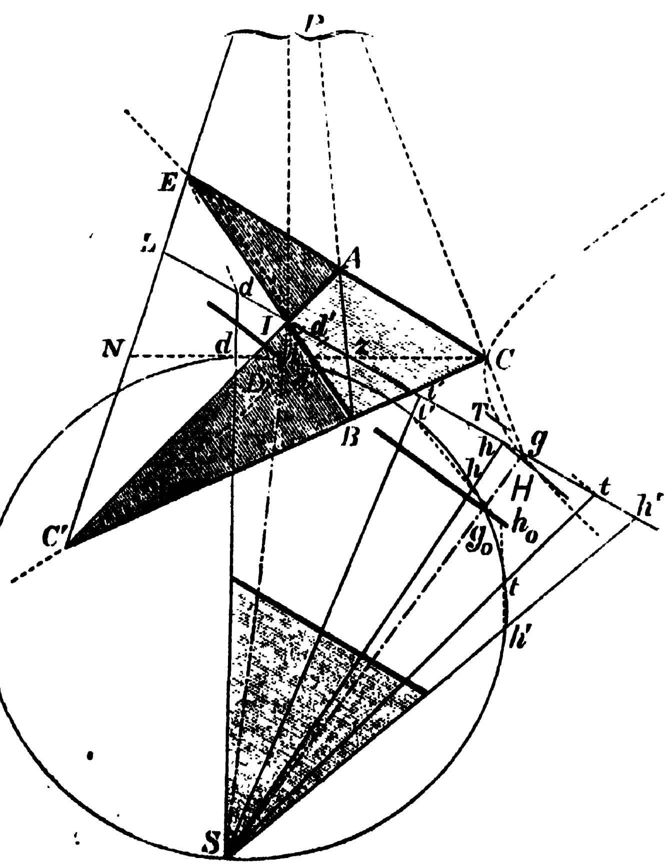

FIG. 2.

on the hyperbola, it is possible to find the point of intersection I of the given transversal Lz with the hyperbola without constructing the curve. First describe any circle in the plane of the five points, choosing two of these, such as E and i, as centres of projection from which to project the remaining three points DHT upon the given transversal Lz in the points dht

and $d'h't'$ respectively. Then, from any point S on the circumference of the circle, reproject the six points dht, $d'h't'$, upon the same circumference in the points similarly lettered.

By means of this double projection from the centres E and i the points DHT have been transferred in duplicate from the hyperbola to the circle, or from one conic to another of a different species; and it is proved in treatises on modern geometry that points so transferred lose none of their projective properties. Hence the points dht and $d'h't'$ on the circumference of the circle are allied projective systems. Therefore, in order to find the perspective line common to both systems, choose one point t of the first set as the centre of projection of the second system; and make t', the correlative point of the second set, the centre of projection of the system dht.

From t project the points d' and h' by rays td' and th', and from t' project the correlative points d and h by rays $t'd$ and $t'h$. Then the correlative rays td' and $t'd$ will intersect in a point d_0 on the required perspective line; and the correlative rays th' and $t'h$ will meet in h_0, a second point on the same line. This perspective line d_0h_0 will intersect the circumference in two points i_0 and g_0 which, being joined to S and produced, will determine the double points I and g common to the hyperbola and transversal Lz. The complete quadrangle EC'IC shows that the harmonic ratios CziN and gzIL are segments of the same harmonic pencil P.

The lines Ez and C'z are tangents to the curve at E and C' respectively; and z is the pole of the polar EC' with respect to the hyperbola. The proofs of these last two deductions may be found in any good text-book on geometry of position.

ROBERT H. GRAHAM.

Thought and Breathing.

PROF. MAX MÜLLER's article on thought and breathing, in your issue of February 6 (p. 317) has just come into my hands. In it he states that the power of retaining the breath is practised largely by Hindus as a means towards a higher object, viz. the abstraction of the organs of the human body from their natural functions. The same custom prevails amongst a certain sect of Mahometans also—the so-called Softas.

In 1878, when in the Central Provinces of India, I came across a native Christian—Softa Ali, as he was called—who had a history. His father had been a Cazi—or religious judge—and a wealthy man, who through scruples of conscience fell into disgrace with a certain native ruler, lost his all, and was banished. His son was, or became, a Softa, and after some years embraced Christianity from conviction, and at great cost to himself—for his wife and children would no longer consort with him. When describing to me the practices formerly enjoined upon him by his religion, this man stated that a Softa is required to draw in and retain his breath and respire it again in various manners. He did not give full details as to how this should be effected, but said that the object of this procedure was to worship with every organ of one's body—heart, lungs, &c., in turn. He added that this practice was a fruitful source of heart-disease.

The following year, when staying at Futtehpore Sikri, near Agra, I saw and heard a Mahometan, unknown to himself, make his evening devotions near the tomb of Suleem Chisti in the way above described; his movements, and the sounds he uttered, were most peculiar.

It has been often related, from well-attested evidence, that in the case of those who have been recovered from drowning, or of those who have been hung and cut down before life was extinct, a kind of automatic consciousness seems to be extraordinarily active in them at the time of their peril. It would appear that, as regards Hindu and Mahometan devotees, and the drowning or partially hung man, a kind of asphyxia is the result, and that, when sensation is almost gone, the intelligence acquires increased activity. In our ordinary life, if our minds are intently fixed upon a subject, we instinctively and involuntarily retain the breath.

When in Rajputana, and again when on the frontier of Chinese Tibet, I saw in each place a man who, to all appearance, seemed to have attained the power of perfect abstraction. In the former case, the villagers asserted that the devotee rose only once a week from his most uncomfortable and constrained position; in the second instance, the man—a most singular-looking person—remained absolutely immovable the whole day. Both seemed to be in a kind of cataleptic trance.

HARRIET G. M. MURRAY-AYNSLEY.

Former Glacial Periods.

I HAVE long felt convinced that geologists are being misled in reference to former glacial epochs by failing to give due thought to a consideration referred to on former occasions,[1] viz. that when the present surface of the globe has been disintegrated, washed into the sea, and transformed into rock, there will undoubtedly then be about as little evidence that there had been a glacial epoch during post-Tertiary times as there is at present that there was one during Miocene, Eocene, Permian, and other periods.

JAMES CROLL.

Perth, March 6.

[1] Quart. Journ. Geol. Soc. for May 1889; "Climate and Time," p. 266.

AUSTRALASIAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE formation of this Association, mainly by the efforts of Prof. Liversidge, of Sydney University, and its first meeting in Sydney in August 1888, were noticed at the time in NATURE (vol. xxxviii. pp. 437, 623). One of the chief rules of the Association is that it shall meet in turn in the capital cities of the various colonies; and Melbourne was agreed upon as the second meeting-place. It was found inconvenient, however, to hold the Melbourne meeting during 1889, as should have happened in due course, for it is only after Christmas that all the Universities are simultaneously in vacation; and accordingly it was commenced on the 7th of January in the present year, and was continued through the following week. Some anxiety was felt as to the result of this choice of date, for there is always a risk in January of such continuous heat as would hinder the work and destroy the pleasure of the meeting; but the Association proved to be specially favoured in the matter of weather.

The following are the names of the officers of the Association and of the Sections. With regard to the latter, the rule obtains that Presidents are chosen from other colonies, while Vice-Presidents and Secretaries are chosen from the colony in which the meeting is held.

President, Baron von Mueller, K.C.M.G., F.R.S.

Local Treasurer, R. L. J. Ellery, C.M.G., F.R.S.

General Secretaries: Prof. Archd. Liversidge, F.R.S., Permanent Hon. Secretary; Prof. W. Baldwin Spencer, Hon. Sec. for Victoria.

Assistant Secretary for Victoria, J. Steele Robertson.

Sectional Officers:—Section A (Astronomy, Mathematics, Physics, and Mechanics)—President, Prof. Threlfall, Sydney University. Vice-President, Prof. Lyle, Melbourne University. Secretaries: W. Sutherland, E. F. J. Love.

Section B (Chemistry and Mineralogy)—President, Prof. Rennie, Adelaide University. Vice-President, C. R. Blackett, Government Analyst, Melbourne. Secretary, Prof. Orme Masson, Melbourne University.

Section C (Geology and Palæontology—President, Prof. Hutton, Canterbury College, New Zealand. Vice-President, Prof. McCoy, C.M.G., F.R.S., Melbourne University. Secretary, James Sterling,

Section D (Biology)—President, Prof. A. P. Thomas, Auckland. Vice-Presidents: J. Bracebridge Wilson; P. H. MacGillivray. Secretaries: C. A. Topp, Arthur Dendy.

Section E (Geography)—President, W. H. Miskin, President of the Queensland Branch of the Royal Geographical Society of Australasia. Vice-Presidents: Commander Crawford Pasco, R.N.; A. C. Macdonald. Secretary, G. S. Griffiths.

Section F (Economic and Social Science and Statistics—President, R. M. Johnson, Registrar-General, Hobart. Vice-President, Prof. Elkington, Melbourne University. Secretaries: A. Sutherland, H. K. Rusden.

Section G (Anthropology)—President, Hon. J. Forrest, C.M.G., Commissioner for Crown Lands, Western

Australia. Vice-President, A. W. Howitt, Secretary for Mines, Melbourne. Secretary, Rev. Lorimer Fison.

Section H (Sanitary Science and Hygiene)—President, Dr. J. Ashburton Thompson, Sydney. Vice-Presidents: A. P. Akehurst, President of the Central Board of Health Melbourne; G. Gordon. Secretary, G. A. Syme.

Section I (Literature and Fine Arts)—President, Hon. J. W. Agnew, Hobart. Vice-Presidents: Prof. Tucker, Melbourne University (Literature Sub-Section); J. Hamilton Clarke (Music Sub-Section). Secretaries: Dr. Louis Henry (Music Sub-Section); Tennyson Smith (Literature Sub-Section).

Section J (Architecture and Engineering)—President, Prof. Warren, Sydney University. Vice-Presidents: A. Purchas, H. C. Mais. Secretary, A. O. Sachse.

All arrangements for the meeting were made by the Local Committee, of which Mr. R. L. J. Ellery, the Government Astronomer, was chairman, and Prof. W. Baldwin Spencer secretary. The greater share of the work devolved on Prof. Spencer, and to his indefatigable energy is mainly due the undoubted success of the meeting. The buildings and grounds of the University were placed at the service of the Association, and nothing could have been better than the accommodation thus afforded. A lecture theatre was set apart for each of the ten Sections; and, as these theatres are situated in different parts of the grounds, and some distance apart, they were all connected by telephone, so that the advent of each paper in any Section could be signalled in every other. The large Wilson Hall was used as a reception-room; and a luncheon-hall, smoking-rooms, reading- and writing-rooms, a press-room, &c., were also provided, as also a special post- and telegraph-office. An official journal of the proceedings was published each morning, and every member was supplied with a copy of a special hand-book compiled for the occasion, and containing the following chapters:—

(1) "History of Victoria," by Alexander Sutherland.
(2) "Geology of Melbourne," by G. S. Griffiths.
(3) "Aborigines of Victoria," by Lorimer Fison.
(4) "Zoology, Vertebrata," by A. H. S. Lucas.
(5) "Zoology, Invertebrata," by A. Dendy.
(6) "Entomology," by C. French, Government Entomologist.
(7) "Botany," by C. A. Topp.
(8) "Commerce and Manufactures," by W. H. Thodey.
(9) "Climate," by R. L. J. Ellery, C.M.G., F.R.S., Government Astronomer.

Over six hundred members, representing all parts of Australasia, were in actual attendance, the total membership roll numbering more than a thousand. Some hundred and fifty papers in all were set down for reading in the various Sections. All these figures show a large increase since the first meeting, and give gratifying evidence of the growing interest taken in science throughout the colonies; further proofs of which are to be found in the facts that the Government of Victoria voted the liberal sum of £1000 towards defraying the expenses of the meeting, and that the entertainments provided by the hospitality of prominent citizens were numerous and on a most sumptuous scale. Many visits to places of scientific interest were also arranged for—short afternoon excursions for those who might not care for continuous Sectional work, and longer excursions at the conclusion of the meeting, under special leaders, to the Australian Alps, the Black Spur and Marysville, Gippsland Lakes, Ferntree Gully, Ballarat, and Sandhurst, all of which proved highly successful.

At the opening meeting in the Town Hall—presided over by His Excellency the Governor, the Earl of Hopetoun—the President, Baron Sir Ferdinand von Mueller, delivered his address, after being introduced by his predecessor in office, Mr. Russell, the Government Astronomer of New South Wales. Baron von Mueller undoubtedly stands at the head of the scientific workers in Australia. He has been a colonist since 1848, and since 1852 has held the position of Government Botanist in Victoria. His fame, which is based not only on the immense amount of work he has done in his special subject, the botany of Australia, but on his early achievements as an explorer, may be indicated in the words used by Mr. Russell:—"In 1861 he was made a Fellow of the Royal Society; he received from Her Majesty the Queen the Knight Companionship of St. Michael and St. George; was made a Commander of the Orders of St. Iago of Portugal, of Isabella of Spain, and of Philip of Hesse; was created hereditary Baron by the King of Würtemberg in 1871; and is honorary or corresponding member of a hundred and fifty learned societies." To this enumeration may be added what is, perhaps, the most honourable award of all—that of a Royal Medal by the Royal Society at the end of 1888. Throughout the colonies "the Baron" is known: a unique personality, not always wholly understood, but always recognized as a proud possession. His address, therefore, was listened to with peculiar interest, and perhaps all the more so that he did not confine himself to any special branch, but dealt generally with the past and future of Australasian science.

The Presidents of Sections also, in many cases, chose for their addresses subjects of particular interest in Australia. Prof. Rennie spoke of the work that has been done in the investigation of the chemistry of native plants and minerals, and made suggestions as to how this work may in future be encouraged and facilitated. Prof. Thomas discussed the problems here awaiting the biologist, and the local desiderata in scientific education. Mr. Miskin spoke principally of exploration in Australia and New Guinea, and of the importance to the colonies of Antarctic exploration; but he also discussed the chief geographical work now being done in other parts of the world. Mr. Forrest's address dealt with the present condition of the Australian aboriginal races. Dr. Ashburton Thompson discussed the sanitary organizations of Victoria and New South Wales, and the modes of obtaining and interpreting health statistics. Prof. Warren spoke of the education of engineers, with special reference to the local conditions and requirements. Dr. Agnew reviewed the literature and art of Australia. In the other Sections the Presidents chose subjects that do not owe their interest to local colour. Prof. Threlfall gave an account of the present state of electrical knowledge; Prof. Hutton's address was on the oscillations of the earth's surface; and Mr. Johnston spoke generally of current social and economic problems. A large proportion of the papers read by members in the various Sections were also Australian in their character. This was specially the case in the Sections of Geology and Anthropology; where, perhaps, the most valuable original work was communicated. As the Transactions will soon be published, the individual papers need not now be noticed; but reference may be made to the work done in the form of reports from Committees appointed at the previous meeting. The most bulky and perhaps the most valuable of these reports is that by a Committee which undertook, with Prof. Liversidge as its secretary, to prepare a census of the known minerals of the Australasian colonies. It disposes of New South Wales (only such information being given as was required to supplement Prof. Liversidge's published work), Queensland, and New Zealand. The portions dealing with Victoria and Tasmania are in process of completion; and, the Committee having been re-appointed, it is hoped that by next year the whole census will be complete. The publication will probably be delayed till then, and it will if possible take the form of a separate volume. A very important recommendation was made by another Committee (Prof. Haswell, of Sydney, secretary), which when

it is carried out will do much for biological research, viz. that steps be taken to establish and endow a central biological station at Port Jackson. Among the other reports may be mentioned one on the Polynesian races and Polynesian bibliography.

At the final meeting of the General Committee of the Association new special Committees were appointed to investigate and report on the following subjects: wheat rust, the manner of laying out towns, the preparation of geological maps, the arrangement of museums, the fertilization of the fig, Australian tides, and the present state of knowledge with regard to Australasian palæontology. A Committee was also appointed to formulate a scheme for obtaining practical assistance from the various Colonial Governments in the collection of material for research—chemical, geological, or biological. Other special Committees were appointed for the publication of the Transactions and for the revision of the laws of the Association.

The next meeting is to be held in Christchurch, New Zealand, probably in January 1891; and Sir James Hector has been elected President, and Prof. Hutton, Secretary. It has also been decided to hold the fourth meeting in Hobart, Tasmania, so that the Association will not again meet on the mainland for three years. To adventure so far as Christchurch is somewhat bold in so young an Association; but the success of the Melbourne meeting has demonstrated its usefulness and popularity, and warrants the belief that many will cross the water next year. There is even a strong hope felt by some that the occasion and the place may tempt a few of the members of the parent British Association to make the longer voyage from home, and see for themselves what is being done and what waits to be done for science at the antipodes.

ORME MASSON.

METEOROLOGICAL REPORT OF THE "CHALLENGER" EXPEDITION.[1]

PREVIOUS to 1872, discussions of the fundamental problems of meteorology relating to diurnal changes in atmospheric pressure, temperature, humidity, wind, and other phenomena, may be regarded as restricted to observations made on land. It had then, however, become evident that data from observations made on land only, which occupies about a fourth part of the earth's surface, were quite inadequate to a right conception and explanation of meteorologieal phenomena; and hence, when the *Challenger* Expedition was fitted out, arrangements were made for taking, during the cruise, hourly or two-hourly observations. These observations were published in detail in the "Narrative of the Cruise," Vol. II. pp. 305–74, and are still by far the most complete yet made on the meteorology of the ocean.

Elaborate observations were likewise made on deep-sea temperatures, which were at once recognized as leading to results of the first importance in terrestrial physics, and opening for discussion the broad question of oceanic circulation, on a sound basis of authentic facts. Preliminary, however, to any such inquiry, a full discussion of atmospheric phenomena was essential, requiring for its proper handling maps showing the mean temperature, mean pressure, and prevailing winds of the globe for each month of the year, with tables giving the data from which the maps are constructed. In other words, what was required was an exhaustive revision and ratification of Dove's isothermals, 1852; Buchan's isobars and prevailing winds, 1869; and Coffin's winds of the globe, 1875.

[1] "Report of the Scientific Results of the Voyage of H.M.S. *Challenger* during the Years 1873–76." Prepared under the superintendence of John Murray, LL.D. "Physics and Chemistry," Vol. II., Part V. "Report on Atmospheric Circulation." By Alexander Buchan, M.A., LL.D.

The work was entrusted to Mr. Buchan, of the Scottish Meteorological Society, in 1883, and was published in the beginning of this year. In addition to the tables of the appendices, giving the results of the *Challenger* observations, the more important are those giving the mean diurnal variation of atmospheric pressure at 147 stations in all parts of the world; the mean monthly and annual pressure at 1366 stations; a similar table of temperatures at 1620 stations; and the mean monthly and annual direction of the wind at 746 stations. It is believed that these tables include all the information at present existing that is required in the discussion of the broad questions raised in the Report, which includes, with the exception of the rainfall, all the important elements of the climates of the globe.

The Report itself is divided into two parts, the first dealing with diurnal, and the second with monthly, annual, and recurring phenomena. This is the first attempt yet made to deal with the diurnal phenomena of meteorology over the ocean—the temperature, pressure, and movements of the atmosphere, together with such phenomena as squalls, precipitation, lightning, and thunderstorms.

In equatorial and subtropical regions, the mean temperature of the surface of the sea falls to the daily minimum from 4 to 6 a.m., and rises to the maximum from 2 to 4 p.m., the amount of the diurnal variation being only 0°·9 F. In the higher latitudes of the Antarctic Ocean, the diurnal variation was only 0°·2. Of the four great oceans, the greatest variation was 1°·0 in the North Pacific, and the least 0°·8 in the Atlantic. This small daily variation of the temperature of the surface of the sea, shown by the *Challenger* observations, is an important contribution to physical science, being in fact one of the prime factors in meteorology, particularly in its bearings on the daily variations of atmospheric pressure and winds. The diurnal phases of the temperature of the air over the open sea occur at the same times as those of the temperature of the surface, but the amount of the variation is about 3°·0, and when near land the amount rises to 4°·4. The greater variation of the temperature of the air, as compared with that of the surface of the sea on which it rests, is a point of much interest from the important bearings of the subject on the relations of the air, and its aqueous vapour in its gaseous, liquid, and solid states, and the particles of dust everywhere present, to solar and terrestrial radiation. Thus the air rises daily to a higher and falls to a lower temperature than does the surface of the sea on which it rests.

The diurnal variation in the elastic force of vapour in the air is seen in its amplest form over the open sea, the results giving a curve closely coincident with the diurnal curve of temperature. But near land, the elastic force instead of rising towards, and to, the daily maximum at noon and 2 p.m., shows a well-marked depression at these hours, and indicates no longer merely a single, but a double maxima and minima. In other words, the curve now assumes the characteristics of this vapour curve as observed at all land stations, or where during the warmest hours of the day ascending currents rise from the earth's surface, and down-currents of drier air take their place. An important point specially to be noted here is that over the open sea, hygrometric observations disprove the existence of any ascending current from the surface of the sea during the hours when temperature is highest. On the other hand, the curve of relative humidity is simply inverse to that of the temperature, falling to the minimum at 2 p.m. and rising to the maximum early in the morning.

As regards the diurnal variation of the barometer, it is shown that the special forms of the monthly curves are, in their relations to the sun, direct and not cumulative as is the case with most of the monthly mean results of

meteorology. The movement of the daily barometric oscillations from east to west is only quasi-tidal, being quite different from the manner in which the tides of the ocean are propagated from place to place over the earth's surface; these oscillations being, undoubtedly, directly generated by solar and terrestrial radiation in the regions where they occur, and it is thus only that the striking variations in the curves of restricted districts comparatively near each other are to be explained. These peculiarities do not occur over the open sea.

As illustrating these variations, reference is made to the retardation of the time of occurrence of the morning maximum, which is delayed as the year advances, the latest retardation being in June; and the curves of 14 stations are given, these stations being situated in the middle and higher latitudes, and in localities which, while strongly insular in character, are at the same time not far from extensive tracts of land to eastward or south-eastward. These barometric curves for June present a graduated series, the two extremes being Culloden, where the morning maximum occurs at 7 a.m., and Sitka, where the same phase of pressure is delayed till 3 p.m., there being thus eight hours between them. Another set of curves is given from lower latitudes, showing the diurnal variation in mid-ocean from the *Challenger* observations, together with a series of land stations representing the influence of a land surface in increasing the amount of the variation, which reaches the maximum in the driest climates. Latitude for latitude, the maximum daily variation occurs in such arid climates as Jacobabad on the Indus, and the minimum over the anticyclonic regions of the great oceans. At Jacobabad the variation from the morning maximum to the afternoon minimum reaches 0·187 inch, whereas in the South Pacific it is 0·036 inch, and in the North Atlantic only 0·014 inch.

The following are some of the other types of barometric curves discussed—the curves at high-level stations on true peaks, and down the sides of the mountain; the curves in deep contracted valleys; those in high latitudes in the interior of continents where the morning minimum disappears; and those in high latitudes over the ocean where the afternoon minimum disappears. In the two last cases, the curve is reduced to a single maximum and minimum, which as regards the times of occurrence are the reverse of each other.

The atmosphere over the open sea rests on a floor or surface, subject to a diurnal range of temperature so small as to render that temperature practically constant both night and day; but notwithstanding this, the diurnal oscillations of the barometer occur over the open sea, equally as over the land surfaces of the globe. Hence the vitally important conclusion is drawn that the diurnal oscillations of the barometer are not caused by the heating and cooling of the earth's surface by solar and terrestrial radiation and by the effects following these diurnal changes in the temperature of the surface, but that they are primarily caused by the direct heating by solar radiation and cooling by terrestrial radiation of the molecules of the air and of its aqueous vapour, and the changes consequent on that cooling. It follows that these changes of temperature are instantly communicated through the whole atmosphere, from its lowermost stratum resting on the surface to the extreme limit of the atmosphere. There are important modifications of the barometric curves affecting the amplitude and times of occurrence of the principal phases of the phenomena, over land surfaces, for example, which are superheated during the day and cooled during the night according to the amount of aqueous vapour present in the atmosphere. But it is particularly insisted on that the barometric oscillations themselves are independent of any change in the temperature of the floor of the earth's surface on which the atmosphere rests. It scarcely requires to be added that these results of observation will necessitate the revision of all theories of the diurnal oscillations of the barometer that have assumed a diurnal change of the temperature of the surface on which the atmosphere rests as a necessary cause of these oscillations. The theory of the diurnal oscillations of the barometer submitted by Mr. Buchan may be thus stated: Assuming that aqueous vapour, in its purely gaseous state, is as diathermanous as the dry air of the atmosphere, it is considered that the *morning minimum* of pressure is due to a reduction of tension brought about by a comparatively sudden lowering of the temperature of the air itself by terrestrial radiation through all its height, and by a change of state of a portion of the aqueous vapour from the gaseous to the liquid state by its deposition on the dust particles of the air. The morning minimum is thus due, not to any removal of the mass of air overhead, but to a reduction of the tension by a lowering of the temperature and change of state of a portion of the aqueous vapour.

As the heating of the air proceeds with the ascent of the sun, evaporation takes place from the moist surfaces of the dust particles, and tension is increased by the simple change from the fluid to the gaseous state; and as the dust particles in the sun's rays rise in temperature above that of the air-films in contact with them, the temperature of the air is thereby increased, and with it the tension. Under these conditions the barometer steadily rises with the increasing tension to the *morning maximum*; and it is to be noted that the rise of the barometer is not occasioned by any accessions to the mass of air overhead, but only to increasing temperature of the air itself and change of state of a portion of its aqueous vapour.

By and by an ascending current of the warm air sets in, and pressure gradually falls as the mass of air overhead is reduced by the ascending current flowing back as an upper current to eastward—in other words, over the section of the atmosphere to eastward whose temperature has now fallen considerably lower than that of the region from which the ascending current is rising; and this continues till pressure falls to the *afternoon minimum*.

The back flow to eastward of the current, which has ascended from the longitudes where pressure at the time is at the minimum, increases pressure over the longitudes where temperature is now rapidly falling, and this atmospheric quasi-tidal movement brings about the *evening maximum* of pressure, which occurs from 9 p.m. to midnight according to latitude and geographical position. As the early hours of morning advance these contributions through the upper currents become less and less, and finally cease, and the effects of terrestrial radiation now going forward again introduce the morning minimum as already described. It is during the evening maximum that the diurnal maximum of periods of lightning without thunder and of the aurora take place, it being during this phase of the pressure that the atmospheric conditions result in an abundant increase of ice spicules in the upper regions of the atmosphere, which thus serve as a screen for the better presentation of any magneto-electric discharges that may occur.

It is interesting to note, in this connection, that the amount of the diurnal barometric tide falls conspicuously to the minimum, latitude for latitude, within the anticyclonic regions of the great oceans, where, owing to the descending currents which there prevail, deposition from the aqueous vapour is less abundant on the dust particles.

From a discussion of the whole of the two-hourly observations of the wind made during the cruise, sorted into those made over the open sea and those made near land, it is shown that the velocity of the wind is greater over the open sea than at or near land, the difference being from 4 to 5 miles per hour. The most important result is that there is practically no diurnal variation in the wind's velocity over the open sea. But as respects

the winds observed near land, the velocity at the different hours of the day gives a curve as clearly and decidedly marked as that of the temperature, the minimum occurring from 2 to 4 a.m., and the maximum from noon to 4 p.m., the absolute maximum being at 2 p.m. The difference between the hour of least and that of greatest velocity is for the Southern Ocean 6½ miles; South Pacific, 4½ miles; South Atlantic, 3¼ miles; and North and South Atlantic, each 3 miles. It is also to be noted that even the maximum of the day near land in the case of none of the oceans attains to the velocity observed over the open sea. The curve near land is substantially the same as the curves characteristic of stations on land. Thus, over the sea, where surface temperature is practically a constant day and night, the velocity of the wind shows no diurnal variation; whereas over land, and also near it, where the temperature of the surface is subject to a diurnal variation, the wind's velocity is also subject to an equally well-marked diurnal variation. On the other hand, at high-level observatories situated on true peaks, the maximum velocity occurs during the night, and the minimum during the day. In deep valleys in mountainous regions, an abnormally high barometer obtains during the night, which is the result of cold currents from the adjoining slopes that the cooling effects of terrestrial radiation set in motion. Now since these down-flowing winds must be fed from higher levels than those of the mountain itself, the winds prevailing on their tops are really the winds of a higher level, and blow therefore with the increased velocity due to that greater height. On the other hand, during the warmer hours of the day, the barometric pressure in deep valleys is abnormally low, owing to the superheating of these valleys as contrasted with the temperature of the surrounding region, thus giving rise to a warm wind blowing up the valleys, and an ascending current close to the sides of the mountain up to the summit. Now, since no inconsiderable portion of this ascending current, whose horizontal velocity is necessarily much retarded, mingles with the air-current proper to the level of the peak, the wind on the peak is retarded, and falls to the minimum of the day when the temperature is highest.

The results of the averaging of the squalls over the open sea entered in the *Challenger's* log show a strongly marked diurnal maximum early in the morning, when the effects of terrestrial radiation are at the maximum. But over land the diurnal curves for whirlwinds, tornadoes, and allied phenomena, show the minimum at these hours, and the maximum at the hours when insolation is strongest. It is probable that the daily maximum occurs in each case at those hours when temperature decreases with height at a greatly more rapid rate than the normal.

The distribution during the day of thunderstorms, and of lightning without thunder, is very remarkable. During the cruise 26 thunderstorms occurred over the open sea, of which 22 occurred during the 10 hours from 10 p.m. to 8 a.m., and only 4 during the other 14 hours of the day. Hence, over the open sea, the diurnal curve of thunderstorms is precisely the reverse of what obtains on land. Of the 209 reported cases of lightning without thunder, 188 occurred during the 10 hours from 6 p.m. to 4 a.m., and only 21 during the other 14 hours of the day. The following are the hours of the maxima of these phenomena in the warmer months over land and the open sea respectively. Thunderstorms over land, 2 to 6 p.m.; lightning over land, 8 p.m. to midnight; lightning over the open sea, 8 p.m. to 4 a.m.; and thunderstorms over the open sea, 10 p.m. to 8 a.m. These facts are a valuable contribution to the science, from their intimate connection with the ascending and descending currents of the atmosphere.

The second part of the Report, dealing with the monthly and annual phenomena, aims at giving a comparative view of the climatologies of the globe to a degree of completeness not previously attempted. The distribution of the temperature and pressure of the atmosphere and prevailing winds is illustrated by 52 newly constructed maps, of which 26 show by isothermals the mean monthly and annual temperature on hypsobathymetric maps, first on Gall's projection, and second on north circumpolar maps on equal surface projection; and 26 show, by isobars, for each month and for the year, the mean pressure of the atmosphere, with the gravity correction to lat. 45° applied, and by arrows the prevailing winds of the globe. Two other maps are given in the text, one showing for July the geographical distribution of the amount of the barometric oscillation from the morning maximum to the afternoon minimum; and the other, the annual range of the mean monthly pressure, which, in a sense, may be regarded as indicating the relative stability of the atmospheric pressure in different regions of the earth.

For the details of this discussion, we must refer to the Report itself, the broad results of which Mr. Buchan thus summarizes:—

"The isobaric maps show, in the clearest and most conclusive manner, that the distribution of the pressure of the earth's atmosphere is determined by the geographical distribution of land and water in their relations to the varying heat of the sun through the months of the year; and since the relative pressure determines the direction and force of the prevailing winds, and these in their turn the temperature, moisture, rainfall, and in a very great degree the surface currents of the ocean, it is evident that there is here a principle applicable not merely to the present state of the earth, but also to different distributions of land and water in past times. In truth, it is only by the aid of this principle that any rational attempt, based on causes having a purely terrestrial origin, can be made in explanation of those glacial and warm geological epochs through which the climates of Great Britain and other countries have passed. Hence the geologist must familiarize himself with the nature of those climatic changes which necessarily result from different distributions of land and water, especially those changes which influence most powerfully the life of the globe."

It is evident from what has been said that many of the results of the diurnal and seasonal phenomena of ocean meteorology are equally novel and important, and, when combined with the analogous results obtained from land observations, enable us to take a more intelligent and comprehensive grasp of atmospheric phenomena in their relations to the terraqueous globe taken as a whole than has hitherto been possible.

THE BOTANICAL LABORATORY IN THE ROYAL GARDENS, PERADENIYA, CEYLON.

THE attention of the readers of NATURE has been drawn more than once (vol. xxxi. p. 460, vol. xxxiv. p. 127) to the opportunities which are before botanists for the study of plants other than those of our own flora. But since the latter of these articles appeared, a step has been taken which will justify a return once more to this important subject.

It is certainly one of the most healthy signs of the present time that our younger botanists desire not merely to pore over minute details of microscopical structure in the laboratory at home, but to become personally acquainted with plants in the open. When the somewhat sudden reversion occurred some fifteen years ago, from taxonomy as an academic study, to the more detailed examination of the tissues of plants in the laboratory, and the study of their functions, those who took a large view of the progress of the science must have seen with regret that the change, however valuable in itself, brought with it a new danger. Those who as students were first introduced to plants as subjects of microscopic study ran

the risk of failing to appreciate the importance of external form: they acquired a knowledge of the minute structural details of certain plants, but did not acquire a strong grasp of the external characters of plants as a whole. But the pendulum which thus swung rapidly over to an extreme position is now returning to the mean. While duly appreciating the value of microscopic examination, the younger botanists are awake to the advantage, or even the necessity, of a wide knowledge of plants. The whole area of facts upon which those who are now engaged in teaching draw in the course of their lectures is much wider than it was ten years ago, and the extension has, perhaps, been most marked in the province of external morphology.

This being so, there will be no need to press upon the men who are starting upon a career as botanists the importance of a visit to the tropics: they will look upon the collections in our Botanic Gardens, which they are hardly allowed to touch, as only a temporary substitute for a tropical jungle, where they may cut down plants as they please, in order to obtain specimens illustrating mature or developmental characters. Moreover, those characters of a tropical flora which are the most striking and characteristic are often those which must remain entirely unrepresented in our glass houses at home. An expedition to the tropics should, in fact, become a recognized item in the programme of preparation for a career as a teacher of botany.

The advantages offered by the Royal Gardens at Peradeniya have already been pointed out in NATURE (vol. xxxiv. p. 127); but since that article was written steps have been taken by a Committee of the British Association to add to them. Backed by a grant of money, they have undertaken the establishment of a permanent laboratory in which visitors may carry on their work. A room has been set apart for this purpose in the official bungalow by the directorate of the Royal Garden. It has every advantage of position, being placed centrally in the garden, and within easy reach of the herbarium, &c.; while, since it is under the same roof as the Director's office, visitors would have the great advantage of the presence of Dr. Trimen himself as a referee in recognition of the plants of the rich native flora. In this room are to be found such apparatus and reagents as are ordinarily required for laboratory work, and steps are being taken to add other facilities.

The mere mention of these facts will probably suffice to attract those who were not previously aware of them. The chief deterrent will be the cost of the journey. It has already been stated that £200 to £250 will suffice for all expenses of an expedition of six months' duration, while if two club together the individual cost would be considerably smaller. Though the Committee of the British Association have no power to use the money entrusted to them as a personal grant, still it is well known that there are sources from which such grants may be obtained in order to assist those who are engaged on a definite line of research. Bearing all these facts in mind, the value of such an expedition as that to Peradeniya cannot be too strongly urged on those who are about to enter definitely on a career as professed botanists. The widening of view, and opportunity for research, which any man of originality would obtain by it would amply repay him for his expenditure of time and money. Applications for the use of the laboratory, which is at present vacant, should be made to Prof. Bower (University, Glasgow), who is the secretary to the Committee.

THE ASTRONOMICAL OBSERVATORY OF HARVARD COLLEGE.

PROF. EDWARD C. PICKERING has presented to the Visiting Committee the forty-fourth Annual Report of the Director of the Astronomical Observatory of Harvard College. The following are the more important passages:—

Henry Draper Memorial.—The first research on the spectrum of over ten thousand of the brighter stars is now nearly completed and is partially in print. The photographs required for the second research on the spectrum of the fainter stars are also nearly complete. The eleven-inch telescope has been in constant use throughout nearly every clear night in photographing the spectrum of the brighter stars. This work is approaching completion for all stars bright enough to be photographed by means of our present appliances, with the large dispersion now employed. Good progress has also been made with the classification of the spectra, and the study of the slight differences in different stars. By the use of an improved process for staining plates with erythrosin, the yellow and green portions of the spectrum, even of the fainter stars, can be advantageously studied. Numerous experiments have been made with a device for measuring the approach and recession of stars, by means of an achromatic prism in front of the object-glass. Several peculiar spectra have been studied, especially that of ζ Ursæ Majoris. The periodic doubling of its lines seems to be due to the rotation of two components too close to be distinguished by direct observation. The detection of bright lines in one of the stars in the Pleiades suggests a possible explanation of the legend that seven stars were formerly visible in this group.

During last spring an expedition was sent to Peru in charge of Mr. S. I. Bailey, assisted by Mr. M. H. Bailey. A station was selected on a mountain about six thousand feet high and about eight miles from Chosica. All supplies for the station, including water, must be carried by mules for this distance. Two frame buildings covered with paper have been erected, one for an observatory, the other for a dwelling-house. Since May 9 the Bache telescope has been kept at work during the whole of every clear night. 1236 photographs have been obtained. The plan proposed will cover the sky south of $-15°$ four times, once with photographs of spectra having an exposure of an hour, which will include stars to about the eighth magnitude; secondly, with an exposure of ten minutes, giving the brighter stars; thirdly, with charts having an exposure of one hour, permitting a map of the southern stars to the fourteenth magnitude inclusive; and fourthly, with charts having an exposure of ten minutes, including stars to about the tenth magnitude. The weather for the first four or five months was excellent, being clear nearly every evening. Fogs and cloud which often covered the adjacent valleys and the city of Lima did not reach to the top of the mountain. The cloudy season is now beginning and the work will be more interrupted. But nearly one-half of the entire programme has already been carried out. A large number of interesting objects have been detected, among others several stars having bright lines in their spectra. Including the photometric work described below, the amount of material so far collected is unexpectedly large.

Boyden Fund.—The climate of Southern California seems especially favourable to the undertaking desired by Mr. Boyden. An expedition under the direction of Prof. William H. Pickering was accordingly sent in November 1888 to the summit of Wilson's Peak, in the vicinity of Los Angeles. In order that as much useful work as possible might be accomplished, the thirteen-inch telescope and the eight-inch telescope now in Peru were sent to Willows, California, where the total solar eclipse of January 1, 1889, was successfully observed. Forty-seven photographs were obtained by the party during the three minutes of totality, and the instrumental equipment was much superior to any previously used for such a purpose. It was not until May 11, that the large telescope was successfully mounted on Wilson's Peak, by Messrs. E. S. King and Robert Black, but since then it has been kept

at work throughout every clear night. The number of photographs obtained is 1155. The objects photographed are selected from a list of 625 double stars, 143 clusters and other celestial bodies, such as the moon and planets. As these same objects have been repeatedly photographed at Cambridge with the same instrument, an accurate comparison of the atmospheric conditions of the two places may be made. It will of course be impossible to derive a final conclusion until the observations have extended over at least a year, but the evidence already secured shows that in summer results can be obtained at Wilson's Peak which cannot be obtained here. The difference is very pronounced for such objects as the markings on Jupiter. Clusters like that in Hercules are well resolved, so that the individual stars are easily measured, which cannot be done with the best Cambridge photographs. As a test-object the sixth star in the trapezium of the Orion nebula is clearly photographed for the first time. A new variable star has been discovered in the midst of the cluster G. C. 3636. A beginning has been made of the measurements of the position and brightness of the double stars, and it is hoped to extend this work to the clusters, and thus furnish an extensive addition to this department of micrometic astronomy.

Much experimental work has also been done at Cambridge, as is shown by the fact that nearly a thousand photographs have also been taken there. Moreover, the expedition to Peru is largely supported by the Boyden Fund. The meridian photometer will be used to extend two large series of observations to the south pole. These are the "Harvard Photometry," and the zones used in the revision of the *Durchmusterung*. This work will furnish photometric magnitudes of stars as bright as the ninth magnitude in all parts of the sky. The Messrs. Bailey have observed 67 series, one of them including 293 stars. In all, during less than six months, about 6700 stars have been observed, which have required 26,800 settings.

The Bruce Photographic Telescope.—For the last six years experiments have been in progress here on the use of a photographic doublet in the preparation of maps of the stars. The eight-inch telescope now in Peru is of this form and was mounted here in 1885. Since then 4500 photographs have been taken with it. With an exposure of an hour twice as many stars can be photographed as are visible with a telescope having an aperture of fifteen inches, and as many stars as can be photographed in the same time with a telescope of the usual form having an aperture of thirteen inches. Moreover with a doublet a portion of the sky covering twenty-five square degrees can be photographed with good definition, while only three or four degrees can be covered equally well with telescopes of the usual form. The time required to photograph the entire sky will be reduced in the same proportion. With a doublet each hemisphere could be covered in one year with eight hundred plates. In 1885 it was proposed to photograph the entire sky with the eight-inch telescope, enlarging the plates three times. The results would resemble in scale and size the charts of Peters and Chacornac. The generous aid of Miss Bruce mentioned above will permit this result to be attained in the original photographs, without enlargement. A contract has been made with Messrs. Alvan Clark and Sons for a telescope having an aperture of twenty-four inches and a focal length of eleven feet. Meanwhile nineteen foreign Observatories have united in an Astrophotographic Congress to prepare a map of the stars to the fourteenth magnitude with telescopes of the usual form having apertures of thirteen inches. The plans have been matured with great care and skill. The courteous reference to the Bruce telescope and its proposed work by Admiral Mouchez shows that both plans can be carried out without disadvantageous duplication. Doubtless each plan will possess certain advantages over the other. The Bruce telescope will be especially adapted to studying the very faint stars. It is hoped that those of the sixteenth magnitude and fainter can be photographed. Its principal use will probably be for the study of the distribution of the stars, for complete catalogues of clusters, nebulæ, and double stars, and for the spectra of faint stars. The amount of material accumulated will be enormous, and the best method of discussion will form a very difficult and important problem.

NOTES.

THE bulletins relating to the health of Sir Richard Owen, who is suffering from a paralytic stroke, have called forth many expressions of sympathy from the general public, as well as from men of science. Hopes of his recovery are entertained, but at his advanced age the process must necessarily be slow.

A CIRCULAR letter from the Conseil Général des Facultés de Montpellier, issued March 1, 1890, and addressed to the chief learned bodies, sets forth that on October 26, 1289, a Bull of Pope Nicolas IV. "érigeait en *Studium generale* les Facultés de Droit, de Médecine et des Arts, qui existaient déjà depuis longtemps dans notre ville." It is proposed, therefore, as we have already noted, that during the present year the University shall commemorate its entry upon its seventh century. The *fête* will probably be held towards the end of May.

AFTER the reading of the papers at the ordinary meeting of the Royal Meteorological Society on Wednesday, March 19, the Fellows and their friends will have an opportunity of inspecting the Exhibition of Instruments illustrating the application of photography to meteorology, and of such new instruments as have been invented and first constructed since the last Exhibition. The Exhibition will, at the request of the Secretary of the Institution of Civil Engineers, be open in readiness for their meeting on Tuesday evening the 18th instant, and will remain open till Friday the 21st instant.

AN International Exhibition of Mining and Metallurgy will be held this year at the Crystal Palace from July 2 to September 30. The Lord Mayor is the patron, the Duke of Fife the Hon. President, and the list of Hon. Vice-Presidents contains the names of Lord Wharncliffe, Lord Brassey, Lord Thurlow, Sir Frederick Abel, Sir Alexander Armstrong, Sir F. Dillon Bell, Sir Graham Berry, Sir Charles Clifford, Sir James Kitson, Sir Roper Lethbridge, M.P., Sir John Lubbock, M.P., Sir John Pender, Sir E. J. Reed, M.P., Sir Saul Samuel, Sir Warington W. Smyth, Sir Charles Tennant, M.P., Sir Edward Thornton, Sir Charles Tupper, Sir H. Hussey Vivian, and Prof. Roberts-Austen. Mr. Pritchard Morgan, M.P., is chairman, and Mr. Henry Cribb deputy-chairman of the Executive Council, which consists of 20 gentlemen well known in engineering and mining matters. The following are the subjects likely to be included within the scope of the Exhibition:—Machinery, mining in gold and silver, diamonds and precious stones, ironstone and iron-ore mining, the manufacture of iron and steel, lead, tin, copper, and coal mining, petroleum and salt industries, and a number of other kindred subjects. Ambulance practice and the condition of miners will also be illustrated.

A GENERAL meeting of the Society for the Preservation of Ancient Monuments in Egypt will be held at the rooms of the Royal Archæological Institute to-morrow (Friday), at 5 p.m. Attention will be specially called to the wanton excision of portions of the well-known fresco paintings in the tomb of the Colossus on a sledge, dating from the Twelfth Dynasty, or between 2000 and 3000 years B.C., at Der-el-Barsha, the chipping out of cartouches of different Sovereigns from the Sixth

Dynasty tombs at the same place, the mutilations of tombs at Beni Hassan, the malicious removal of curious bas-reliefs at Tel-el-Armana, and other recent acts of vandalism. Such outrages as these ought surely to be made practically impossible. All that is needed is that the matter shall be seriously taken in hand by the Foreign Office.

AN attempt is being made by the Society of Antiquaries of London to raise a fund, the interest of which shall be used from time to time to defray the expense of excavations, or to advance archæological knowledge in such other ways as may seem suitable to the President and Council of the Society. The object is one which ought to commend itself to all who interest themselves in archæology. The Society wants a capital sum of only £3000. Subscriptions should be sent to the treasurer, Dr. E. Freshfield, 5 Bank Buildings, E.C.

MR. GLADSTONE has consented to open the new Residential Medical College at Guy's Hospital on Wednesday, March 26, at 2 p.m.

THE treasures of the Ruskin Museum at Sheffield are being transferred from the small building at Walkley, in which they have hitherto been kept, to more convenient premises. The Museum will be reopened by Lord Carlisle on July 15.

THE March number of the *Kew Bulletin* opens with an account of Indian Yellow, or Purree, about the origin of which there used to be much uncertainty. Some time ago, in consequence of inquiries made in India at the request of the authorities at Kew, the mystery was cleared up; and full information on the subject will be found in the present paper. Another paper deals with Bombay aloe fibre, and there are sections on the commercial value of Ioxa bark, and on barilla.

AN industrial and artistic Exhibition will shortly be opened in Oueno, the most beautiful park in Tokio. M. de Lezey, writing to *La Nature* on the subject from Tokio, says that the Exhibition will be particularly rich in collections of Japanese antiquities.

ON February 22 the Johns Hopkins University celebrated the twelfth anniversary of its opening. It was announced that, of the various pressing needs of the University for expansion, that of the chemical laboratory was to be met by turning over to it for reconstruction the ill-ventilated Hopkins Hall.

THE collections belonging to the Academy of Natural Sciences of Philadelphia grow so rapidly that the accommodation provided for them is wholly inadequate. A new building is to be erected, and the State Legislature has voted $50,000 as a contribution towards the expenditure. It is hoped that another "appropriation" of the same amount will be made, and that the rest of the money required will be privately subscribed.

GERMAN papers announce the death of Dr. Karl Emil von Schafhäutl, Professor of Geology, Mining, and Metallurgy at Munich University, keeper of the geognostic collection of the Bavarian State, and member of the Academy of Sciences. He was not only an eminent physicist and geologist, but also a theoretical musician of some note. He was born at Ingolstadt on February 26, 1803, and died at Munich on February 25 last.

THE death of Victor, Ritter von Zepharovich, is also announced. He was Professor of Mineralogy at the German University of Prague, a member of the Academy of Sciences at Vienna, and author of the "Mineralogical Dictionary of the Austrian Empire," and many valuable mineralogical and crystallographical works. He was born at Vienna on April 13, 1830, and died at Prague on February 24 last.

ON Tuesday evening, Dr. Dallinger delivered an interesting lecture at the Royal Victoria Hall, on "The Infinitely Great and the Infinitely Small," to an audience numbering about 400, composed principally of working men. The lecture was illustrated by numerous lantern-views, and was evidently much appreciated.

IN the *Engineer* of the 7th inst., there is an excellent article on the latest express compound locomotive on the North-Eastern Railway. This engine is for the east coast Scotch traffic on the section between Newcastle and Edinburgh—about 125 miles. A trial was made with a train of thirty-two coaches (total weight of train 270 tons) between Newcastle and Berwick, a distance of sixty-seven miles; and the time was seventy-eight minutes, or three minutes less than the Scotch express. With the heaviest loads an assistant engine will not be necessary. In another trial with a special train of eighteen six-wheeled coaches, a speed of about ninety miles per hour was obtained. This is the highest recorded speed by several miles. Diagrams were taken at various speeds, one set at a speed of eighty-six miles per hour on the level. This speed was carefully measured by stop-watch and mile-posts; the highest speed observed was just over ten seconds per quarter mile run. It is evident from these facts that passengers to the north will not waste much time on the journey when the summer traffic begins on the east coast route.

SOME time ago we referred to a paper in which Dr. Daniel G. Brinton developed the theory that the ancient Etruscans were an offshoot or colony of the Libyans or Numidians of Northern Africa—the stock now represented by the Kabyles of Algeria, the Rifians of Morocco, the Touaregs of the Great Desert, and the other so-called Berber tribes. This paper Dr. Brinton has followed up by another, in which he compares the proper names preserved in the oldest Libyan monuments with a series of similar names believed to be genuine Etruscan. The resemblances in many cases are certainly striking, and Dr. Brinton's ideas on the subject deserve to attract the attention of scholars.

AT a meeting of the Royal Botanic Society on Saturday, reference was made to a very interesting collection of seeds of economic and food plants, timber trees, &c., of Uruguay, presented by Consul Alex. K. Mackinnon. On the table were plants in flower of *Narcissus poeticus*, lately received from China, and several varieties of the same flower from the Scilly Isles, illustrating the cosmopolitan nature of this family of plants. In the Scilly Isles narcissi are grown by the acre, and over ten tons of the flowers are sent off weekly to market.

IN the current number of the *Revue des Sciences naturelles appliquées*, M. Mégnin has a valuable paper on the existence of tuberculosis in hares. About two years ago he described a peculiar disease brought on by the presence of some species of *Strongylus* in the lungs of hares. The disease dealt with in the present paper is wholly different.

M. H. BEAUREGARD, *aide-naturaliste* in the Paris Museum of Natural History, has published an elaborate monograph on the Vesicant tribe of insects. It is illustrated by many fine plates.

THE skeleton of a mammoth has been discovered in the Russian province of Tula, and the Moscow Society of Naturalists have sent a commission to excavate it.

MESSRS. MACMILLAN AND CO. are issuing a thoroughly revised edition of "A Treatise on Chemistry," by Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S., and have just published Part II. of Vol. III., dealing with the chemistry of the hydrocarbons and their derivatives. Since this part of the work was published in 1884, many additions have been made to our knowledge of this department of organic chemistry; and the authors, as they themselves explain, have sought to represent the present position of the science by introducing the results of the latest and more important researches, with the effect that the greater part of the volume has been re-written.

MR. JOHN MURRAY has published the nineteenth edition of "The Reign of Law," by the Duke of Argyll.

THE *Amateur Photographer* has issued its fourth "home portraiture number." It reproduces one photograph each from the work contributed by sixty competitors for prizes.

IN the Report of the U.S. Commissioner of Education for the year 1887–88 it is stated that 48 educational institutions in the United States receive the benefit of the national land grant of 1862. Among these institutions are the Arkansas Industrial University, the State Agricultural College at Colorado, the Maine State College of Agriculture and the Mechanic Arts, the Massachusetts Institute of Technology, the Missouri School of Mines and Metallurgy, and the Scientific School of Rutgers College. In 38 of the Colleges an officer of the Army or Navy is detailed to act as professor of military science and tactics. If a State has more than one school endowed by the national land grant of 1862, the school which is reported by the Governor of the State as most nearly meeting the requirements of existing law is held to have the first claim to the officer allotted to the State.

M. A. ANGOT, of the French Meteorological Office, has published in the *Annales* of that office a very careful discussion of the diurnal range of the barometer, based upon the best available data for all parts of the globe. After having given the mean range for each month and for the year, he has calculated the amplitudes and phases of the first four simple harmonic oscillations into which the complex oscillation of the barometric diurnal range may be resolved, and which may be considered as the resultant of the superposition of two waves of different origin and character. One of these, which the author terms the thermic wave, is of a more or less complicated form in appearance, and is easily explained as being produced by the diurnal variation of temperature and by the differences that this variation presents between neighbouring stations. The other, the principal semi-diurnal wave, for which he has given the numerical law, presents a much more simple form, and is not at all affected by local conditions. It is possibly produced by the calorific action of the sun upon the upper strata of the atmosphere; but, as the author states, this is still only an hypothesis, and the theory of this part of the phenomenon remains to be established. His conclusions upon the effect of the thermic wave are very interesting, and the whole discussion will well repay a careful study.

MR. T. W. BAKER writes to us that, in his note regarding the meteor of March 3, he omitted to state the time of its appearance, which was 7.28 p.m.

AN important paper upon the crystalline allotropic forms of sulphur and selenium is contributed by Dr. Muthmann, of Munich, to the latest number of the *Zeitschrift für Krystallographie*. Besides the well-known rhombic pyramids and monoclinic prisms, sulphur may, under certain conditions, be obtained in a third crystalline modification, which has been termed by Gernez "*soufre nacré*." This third modification has been fully investigated by Dr. Muthmann, and, in addition, a new fourth totally distinct variety has been discovered. The third form is best obtained by boiling about five grams of powdered sulphur with 750 c.c. of absolute alcohol in a flask provided with an inverted condenser for one hour, filtering through a warmed funnel into a large flask heated to 70° C. in a water-bath, and allowing the alcohol to slowly evaporate. After about twelve hours a large deposit of brilliant tabular crystals is formed. Similar crystals of the third variety may be obtained by agitating a saturated alcoholic solution of ammonium sulphide with excess of powdered sulphur, filtering, diluting with a little alcohol and allowing to stand in a loosely covered cylinder. In a few hours crystals are found deposited, often measuring a couple of centimetres in length and 1–2 mm. thick. Another method which yielded very beautiful crystals of this modification consisted in allowing a solution of acid potassium sulphate to slowly diffuse into a solution of sodium thiosulphate. In about four weeks' time, perfect crystals, almost white in appearance, and exhibiting strongly the mother-of-pearl lustre, were obtained. This third variety of sulphur also crystallizes in the monoclinic system. The ratio of its axes is $a : b : c = 1{\cdot}0609 : 1 : 0{\cdot}7094$. The axial angle $\beta = 88° 13'$. The symmetry plane, $b = (010) \infty \mathrm{P} \infty$, is so largely developed as to give the crystals the appearance of plates. At the edges of the plates the two primary pyramids $(111) - P$ and $(\bar{1}11) + P$, a prism $(210) \infty P 2$, and a clinodome $(012) \frac{1}{2} \mathrm{P} \infty$ are well developed. These crystals are totally distinct from those of the second modification; the axial ratios of the latter are $a : b : c = 0{\cdot}9957 : 1 : 0{\cdot}9998$ and $\beta = 84° 14'$. Upon the sides of the vessel containing the alcoholic ammonium sulphide solution prepared as above, Dr. Muthmann noticed curious tabular crystals of hexagonal section, which immediately became altered upon contact with a disturbing body, such as a platinum wire or glass rod. They were likewise found to consist of pure sulphur, and, on optical and goniometrical examination, were found to consist of a distinct fourth modification, also monoclinic. They greatly resemble a rhombohedron with predominating basal plane. They are best obtained by allowing to slowly evaporate in a tall cylinder a saturated solution of sulphur in alcoholic ammonium sulphide diluted with four times its volume of alcohol. The temperature during this crystallization must not exceed 14° C. Occasionally in this experiment all four forms of sulphur are obtained; the surface is covered with crystals of the third variety, tables of the fourth modification are deposited upon the sides, and the base of the cylinder is spangled with rhombic pyramids interspersed with monoclinic needles of the second form. If crystals of the third variety are suspended in their mother liquors and left for some days, they are converted into a voluminous mass of minute rhombic pyramids. The conversion into the more stable rhombic form is almost instantaneous if a rhombic crystal be dropped into the liquid containing suspended third variety crystals. The immediate alteration of crystals of the fourth kind is even more remarkable, the mere movement of the cover-glass, when examining them under the microscope, being sufficient to instantly change the optical properties to those of the rhombic form. It is interesting that this fourth form of sulphur is isomorphous with the form of selenium obtained by evaporation of a hot saturated solution in carbon bisulphide.

THE additions to the Zoological Society's Gardens during the past week include two Badgers (*Meles taxus*) from Ireland, presented by Mr. P. Bicknell; a Grey Hypocolius (*Hypocolius ampelinus* ♂) from Scinde, presented by Mr. W. D. Cumming; a Rhesus Monkey (*Macacus rhesus* ♂) from India, a Spotted Ichneumon (*Herpestes nepalensis*) from Nepal, deposited; an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on March 13 = 9h. 25m. 55s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) { G.C. 1861	—	White.	9 25 47	+21 58
G.C. 1863	—	White.	9 25 58	+22 0
(2) 8 Leo Minoris ...	5·7	Reddish-yellow.	9 24 51	+35 35
(3) ι Hydræ	4	Whitish-yellow.	9 34 12	− 0 39
(4) ο Leonis...	4	Yellowish-white.	9 35 18	+10 24
(5) 132 Schj.	Var.	Red.	10 32 7	−12 25

Remarks.

(1) Described by Herschel as a bright extended nebula with two nuclei, the north following one being very faint. In 1848, Lord Rosse observed that the nebula was distinctly spiral, and his drawing represents it as elliptical in shape. The nebula is about 3′ long and is situated about 2° south of the star λ Leonis. I am not aware that any record of the spectrum has been published.

(2) A star of Group II. Dunér states that the bands 2, 3, 7, 8 are visible, but are rather weak and not very wide. The bands 4 and 5 are very delicate. The star belongs to species 5 of the subdivision of the group, which means that the meteor-swarm of which the "star" is probably composed is somewhat sparse. The bright carbon flutings should therefore be well developed. Bright lines may possibly also be present, if the swarm is not too far condensed.

(3) Konkoly and Vogel both describe the spectrum of this star as a well-developed one of the solar type. The usual differential observations are required.

(4) A star of Group IV. (Vogel). The usual observations of the relative thicknesses of the hydrogen and other lines are required.

(5) A star of Group VI., with a spectrum of extraordinary beauty (Dunér). The spectrum consists of four zones, and all the bands 1–10 are strongly developed. Band 6 is not very dark. The specific differences in stars of this group have not yet been fully investigated. The principal variations so far observed are: (1) the length of continuous spectrum, as indicated by the number of zones visible; (2) the number and intensities of the secondary bands; (3) the intensity of band 6 as compared with bands 9 and 10.

Gould believes this star to be variable, his estimates of the magnitude varying between 4·3 and 6·1. Birmingham's values vary from 4·5 to 6·3. The star appears to be U Hydræ, and, if so, a maximum will be reached about March 18 (*Observatory Companion*, 1890). Espin believes the period to be about 195 days.

As yet, we have no information as to changes of spectrum accompanying changes of magnitude in stars of this group.

A. FOWLER.

THE SOLAR AND THE LUNAR SPECTRUM.—Prof. Langley's second memoir on this subject, which was read before the National Academy of Science in November 1886, has been received. In a previous memoir it was demonstrated that evidence of heat had been found in the invisible spectrum of the sunlit side of the moon, and the experiments indicated that this heat was chiefly not reflected but radiated from a surface at a low temperature. The amount of heat, however, was excessively minute, even when compared with the feeblest part of the solar spectrum known in 1882, yet it was easily recognizable because of the fact that, whereas in the typical solar spectrum heat is greatest in the short wave-lengths, in the typical lunar spectrum heat is greatest in the long wave-lengths.

In this second memoir the results of further observation of the infra-red solar spectrum are given, the newly investigated region being close to that which contains a large part of the lunar heat. The researches considerably extend those previously made. In passing from the visible part of the spectrum into the infra-red region, wider regions of absorption occur. To an eye which could see the whole spectrum, visible and invisible, the luminous part would be, as is well known, interrupted by dark lines, the lower part to 5 μ would appear to consist of alternate dark and bright bands, and the part below 5 μ be nearly dark, but with feeble "bright" bands at intervals. This appearance is shown in a plate accompanying the memoir. It is noted as a curious fact that the centres of several of the bands or lines are under some conditions found to be shifted to a recognizable extent, and hence their wave-lengths are, within certain limits, variable. This apparent shift is found to be because the absorption does not increase symmetrically with the centre of the band, but more on one side than another, so as to considerably modify the position of greatest absorption.

THE CORONA OF 1889 DECEMBER 22.—The March number of the *Observatory* contains a Woodburytype reproduction of this corona taken by the late Father Perry with a short focus reflector of Mr. Common's, and a note by Mr. W. H. Wesley, assistant secretary of the Royal Astronomical Society, upon its prominent features. Mr. Wesley finds that, as in the eclipse of January 1, 1889, the extension is greatest towards the equatorial regions, and on the longest exposed plate it can be traced to nearly a diameter from the limb. A wide rift at the north pole, extending 60° or 70° along the limb, contains several fine straight rays similar to the polar rays in 1878 and 1889 January 1, but not so numerous, regular, or distinct. The usual polar rays are scarcely distinguishable at the south pole. A remarkable fact is that the general mass of the corona on the eastern side is considerably broader from north to south than on the western side. This was also the case in 1878. Numerous prominences are seen on the eastern limb, and plates taken near the end of totality show a range of low prominences on the western limb. An interesting feature in the plates taken with the reflector is the photographic reversal of the prominences and the brighter parts of the corona. In the larger exposed negatives the prominences and the corona near the limb are bright instead of dark, whilst the limb itself is bounded by a very definite dark line indicating a double reversal.

THE NEBULAR HYPOTHESIS.—Mr. Herbert Spencer contributed an essay on Laplace's famous theory to the *Westminster Review* for July 1858. With the assistance of Mr. Thynne Lynn, a new edition of this essay has been prepared and distributed amongst leading astronomers at home and abroad.

The revised calculations bring out more strongly than ever Mr. Spencer's views of the nebular hypothesis, and in particular the portion referring to Mars. When the essay first appeared the density of this planet was taken as 0·95, but recent and more exact determinations show the value to be much too high, and taking this into account the fact comes out that to agree with Mr. Spencer's views Mars should have from one to four satellites as it has since 1877 been known to have.

Olbers's theory that the asteroids are fragments of an exploded planet is favoured, and the genesis of the thirteen short-period comets is found in the same catastrophe. It is needless to say that the theory is defended in a most masterly manner, although the arguments against its acceptation are overwhelming.

NEBULA, GENERAL CATALOGUE NO. 4795.—The Journal of the Liverpool Astronomical Society for December 1889, which has just been issued, contains a note by Mr. W. E. Jackson on this nebula, R.A. 22h. 24m., N.P.D. 111° 24′. It is described in the General Catalogue as "Remarkable, pretty faint, very large, extended or binuclear." Mr. Jackson has carefully observed the nebula several times, and finds that there are several stars involved, although no mention of them is made in the Catalogue, and that there is a strong suspicion of others beyond the reach of his 6 inch Grubb telescope. A sketch of the appearance accompanies the note.

A NEW ASTEROID.—Minor planet (284) was discovered by Prof. Luther (Hamburg) on February 24.

CAMBRIDGE ANTHROPOMETRY.

ABOUT two years ago the results were published, in the Journal of the Anthropological Society, of the first batch of measurements taken at Cambridge. These comprised rather more than 1100 cases. During the last two years a nearly equal number have been obtained, and it therefore becomes important to compare the results yielded by these distinct batches.

The measurements proposed by Mr. Galton, and adopted by the Cambridge Committee, were the following:—(1) A test for the eyesight. The extreme distance at which a man could read "diamond type" (viz. the print employed in the little pocket Common Prayer-books) was noted with each eye separately; the figures given in our tables indicate the mean of the two. It may be remarked that, as this instrument would only record up to 35 inches, and as about ten per cent. of the men could read at this distance, it is certain that many could have seen further. The arithmetical mean, therefore, though good enough for our present purposes, is here less scientifically appropriate than the "median." (2) A test of the muscular strength of the arms when employed in an action similar to that of pulling a bow. Two handles, connected at a convenient distance apart, are pulled away from each other against the pressure of a spring. (3) A test of the power of "squeeze" of each hand separately. In this case two handles stand a short distance apart, and are then pressed towards each other against the action of a spring. The figures here given denote the mean of the two results. (4) Measurement of the size of the head. This is taken in three different directions, viz. from front to back, between the two

sides, and upwards from a line between the eye and the ear. The product of these three measurements is what is given in the annexed tables as "head-volumes." It need hardly be said that these numbers do not assign the actual magnitudes of the heads; but they do all that is wanted for our purpose, viz. they are *proportional to* these magnitudes, on the assumption, of course, that the average shape of the head is the same throughout. (5) A test of the breathing capacity. The volume of air, at ordinary pressure, that can be expired is measured by the amount of water displaced from a vessel. The result is given in cubic inches. (6) The height; deducting, of course, the thickness of the shoes. (7) The weight, in ordinary indoor clothing. This is assigned, in our tables, in pounds.

As regards the persons measured, they are exclusively students—that is, undergraduates, with a small sprinkling of bachelors and masters of arts. Nine-tenths of them were between the ages of 19 and 24 inclusive. Statisticians will understand the importance of this fact in its bearing upon the homogeneity of our results; since a comparatively small number of measurements, in such cases, will outbalance in their trustworthiness a very much larger number which deal with miscellaneous crowds.

But it is not so much to the above characteristics that I wish to direct attention here as to one in respect of which our University offers an almost unique opportunity. No previous attempt, it is believed, has ever been made to determine by actual statistics the correlation between intellectual and physical capacities. What, however, with the multiplicity of modern examinations, and the intimate knowledge possessed by many tutors about the character and attainments of their pupils, this could here be effected to a degree which could not easily be attempted anywhere else. By appeal to these sources of information, the students were divided into three classes (here marked as A, B, and C), embracing respectively (1) scholars of their College, and those who have taken, or doubtless will take, a first class in any tripos; (2) those who go in for honours, but fall short of a first class; and (3) those who go in for in for an ordinary degree, to which class also are assigned those who fail to pass. It is not for a moment pretended that such a classification is perfect, even within the modest limits which it hopes to attain. Very able men may fail from indolence or ill-health, and very inferior ones may succeed through luck or drudgery. But it must be remembered that we only profess to deal with averages, and not with individuals, and on average results such influences have little power. There are probably few cricket or football clubs in which one or more men in the second eleven or fifteen are not really better than some in the first, but no one supposes that the second team would have much chance of beating the first. All that is maintained here is that our A, B, C classes, *as classes*, stand out indisputably distanced from each other in their intellectual capacities. The average superiority of one over the next is patent to all who know them, and would be disputed by very few even of the men themselves.

The plan adopted has been to classify the A, B, C men separately, arranging each of these in sub-classes according to their age. On the last occasion about 1100 were thus treated, and it is very important to observe that the new batch (of about 1000) independently confirms the conclusions based on the previous set. Space can scarcely be afforded for these tables separately, so I only give here the results of grouping the entire two sets together. But as a matter of evidence, it must be insisted upon that the two separate tables tell the same tale.

The following, then, are the results of thus tabulating the measurements of 2134 of our students:—

TABLE I.

Class A (487).

No.	Age.	Eyes.	Pull.	Squeeze.	Head.	Breath.	Height.	Weight.
10	18	21·3	75·8	75·3	235·8	244·0	68·13	142·6
42	19	22·6	75·3	80·9	242·9	255·5	69·04	148·0
99	20	23·7	81·2	83·5	242·8	252 7	69·00	152·1
104	21	23·6	81·6	82·8	242·1	255·2	68·82	152·3
94	22	24·6	83·9	87·1	244·3	257·2	68·71	154·0
48	23	21·9	82·0	84·2	242·9	262·8	69·11	149·7
33	24	23·6	84·9	84·0	245·9	261·5	68·90	154·8
57	25	23·0	80·9	82·7	247·2	251·0	68·59	154·6
Average..		23·4	81·5	83·5	243·6	255·6	68 85	152·5

Class B (913).

38	18	24·4	77·4	82·1	236·7	235·0		148·5
136	19	25·4	78·7	80·3	238·0	249·8	68·78	149·7
280	20	24·0	82·5	84·2	237·3	255·1	69·08	153·5
212	21	23·5	83·7	83·7	235·5	257·2	68·84	153·0

57	23	23·8	88·1	87·2	238·5	256·4	68·97	156·2
26	24	25·4	87·4	86·1	239·3	244·0	68·35	156·0
50	25	24·0	82·5	84·2	243·2	247·5	68·24	154·2
Average..		24·4	85·2	84·5	236·8	252·9	68·93	154·8

These tables may be looked at from two points of view, which would commonly be called the practical and the theoretical. By the former, to speak in the more accurate language of statistics, I understand any conclusions to be involved which do not recognize distinctions of less than about 4 or 5 per cent. of the totals in question. Looked at with this degree of nicety, the main fact that the tables yield is, that there is no difference whatever (with a single exception, to be presently noticed) between the physical characteristics of the different intellectual grades. Whether in respect of height, weight, power of squeeze, eyesight, breathing capacity, or head-dimensions, there is no perceptible distinction. There *are* differences, of course, but to say whether or not these are of any significance requires an appeal to the theory of statistics and to tests beyond the reach of the "practical" standard.

The one exception is in the power of "pull." I called attention to this two years ago; but, with the bulk of statistics at that time at our command, I felt somewhat doubtful as to its real significance. But there can scarcely be any doubt as to the non-casual nature of a difference of power between the A and C classes amounting to 4·6 per cent., when this difference displays itself between the averages of such large numbers as 487 and 734 respectively. At least, if there were any doubt, it would be removed by another mode of displaying the results, to explain which a brief digression must be made. In the preceding tables the primary division into three classes was based on intellectual differences. Let us make, instead, one based on physical differences. Let the first class, in respect of each kind of measurement, embrace "the best in ten"; in other words, select the top 200, or thereabouts, in each separate list. Such a table will show, for one thing, the extent to which one kind of physical superiority is correlated with another; and also, by reference to the triposes and tutors' information, it will show how these classes are composed in respect of their A, B, C constituents. The following is such a table, arranged to show how such "first classes" in one physical department stand in relation to the principal other such departments.

TABLE II.

Comparative Excellence in Different Physical Capacities.

	Eyes.	Pull.	Squeeze.	Breath.	Height.	Weight.
1st Class, Eyes	34·6	·86·6	83·5	263·2	69·40	157·1
,, Pull	25·4	113·0	93·9	280·2	·69·82	167·3
,, Squeeze	24·2	96·5	103·7	278·7	70·45	170·1
,, Breath	24·9	94·3	92·4	320·5	71·19	167·3
,, Height	25·3	88·0	90·4	286·7	73·25	171·5
Average student..	24·1	83·5	84·2	254·5	68·94	153·4

I shall call attention hereafter to certain conclusions furnished by this table as to the correlation of these various physical characteristics. At present they are only appealed to in confirmation of the fact alluded to above. It is rather curious that, when we sort out these first classes into their A, B, C constituents, we find that, with the same single exception, the distribution is about what it would be on a chance arrangement. That is, the men of exceptional height or breathing capacity are just as likely to be found amongst the A's as amongst the B's or C's. This is the case even with the eyesight. The first class here was confined to men who could read distinctly the small print (diamond) employed, at a distance of at least 35 inches; with the additional restriction that the weaker eye of the two could read the same at 33 inches. Of such men there were 196 out of 2134. Now had these been taken indiscriminately from the three classes A, B, C, the most likely proportions would have been respectively 44, 84, and 68. The actual numbers were 46, 88, and 62. But when we select in the same way a first class (consisting of 182) of the strongest "pullers," we find that whereas A, B, C, should contribute respectively 41, 78, and 63, they actually contribute 28, 78, and 83. Taken in connection with our previous results, the conclusion seems inevitable that this particular kind of physical superiority is, to a certain extent, for some reason or other, hostile to intellectual superiority.

The question *why* this is so is one which it is not easy to answer with confidence, but the following suggestion may be offered. The action of "pulling" is the only one in the above list of physical tests which is much practised in any popular games: it obviously is so in rowing, whilst in cricket a similar set of muscles appear to be exerted. But no known game appears much to practise our "squeezing" power; and, as regards the height, weight, breathing, and seeing powers, probably any form of exercise which keeps a man in good health offers sufficient scope for development. It would therefore seem to meet all the observed facts if we suppose that our hard-reading men take amply sufficient exercise to develop their *general* physical powers fully up to the same relatively high standard found amongst the others; but that the non-reading men, or a certain proportion of them, are rather apt to devote themselves to certain kinds of exercise which develop a proportional superiority in one special muscular development.

I should not have directed so much attention to this second table if it were not that such considerations have a very direct bearing upon a question of importance at the present day. As some readers of this journal probably know, it has been seriously discussed, in influential quarters, whether it is not advisable to take some account of physical qualifications in our Civil Service or other State examinations.[1] By this, we may presume, is not to be understood any mere *pass* examination. The necessity of some test of that kind may be taken for granted, and would naturally be secured by a medical certificate. Something much more serious than this may plausibly be defended, and on the following grounds.

In most of the examinations of any magnitude with which the State is concerned, it may be taken as a fact of experience that the number of selected candidates bears some moderate ratio to that of those who compete. If two hundred men are found to go in and try, it will seldom be the case that there were very many more or less than fifty vacancies. Supply and demand, in a country in the present social and economic condition of England at any rate, will generally obviate any extreme disproportion between the two quantities. Now it is well known that where many aims of any kind are made at an object the so-called "law of large numbers," or "law of error," comes into play. At the two ends of our list of competitors the discrepancies in their performances will be very great. But, for a wide range on both sides of the middle, the differences will be comparatively small. A glance at any one of the lists, which are published in the papers from time to time, of the selected candidates for the army, with the number of marks gained by each, will illustrate this. Near the top the difference between one candidate and the next may be measured by hundreds of marks, whilst towards the bottom of the selected candidates (*i.e. towards the middle of the competitors*) the difference will be given in tens only, or even in units. So marked is this tendency that any well-informed statistician could often give a very shrewd guess, from the mere inspection of such a list, as to the number of candidates who had failed to pass, and whose names therefore were not mentioned.

Now, this being so, it follows that the differences between, say, the last 20 per cent. who succeeded, and the first 20 per cent. who failed, are extremely slight, *in respect of the qualities thus tested*. Might it not then be wise to take account of some other quality, and what better could be found than the physical? If by sacrificing little or nothing of mental superiority we can gain a good deal of physical superiority, there is much to be said in favour of such a final appeal. If, for instance, we accepted, in the first instance, 20 per cent. more than we wanted to retain, and then subjected the whole number to some physical test, for which a moderate amount of marks were assigned, the men finally excluded would at worst necessarily be those who were only just admitted on the customary plan, and those finally admitted would at worst necessarily be those who otherwise would only just have been rejected.

There is not space here to discuss fully any such proposal, but if any scheme of this kind is ever introduced its justification must rest on considerations such as those displayed in our second table. One or two results may be pointed out. In the first place, it must be insisted that the whole merit of any such scheme rests upon the assumption that mental superiority may be considered as perfectly "independent" (in the mathematical sense) of physical. This we find is *not* quite the case as regards the "pulling" power, but is the case as regards every one of the other qualities here displayed. If we set much store upon tall men, or upon men with good eyes, we may rest assured that little or nothing will be sacrificed in the way of mental results by giving reasonably good marks for such excellence. Again, it may be remarked to what extent these different kinds of physical superiority are correlated. It appears that great superiority in any one kind of physical power is accompanied by considerable superiority in every other. It is a striking fact that in only one of the thirty subdivisions there indicated, do we fail to find the "first class" man, in any one department, standing above the average man in every department.

This being so, it is rather for the physiologist, or for the man of affairs, to select the particular physical test which is likely best to serve the public interest. So far as mere statistics are concerned, I should give the preference to the *breathing power*. For one thing, this appears, in my judgment, to be correlated, on the whole, with a higher general physical superiority than is the case with the other qualities. I apprehend also that good breathing power could not readily be "crammed," so to say, by attendance at a gymnasium, and by aid of professional advice and direction, as can be done to some considerable extent in the case of muscular power.

It has been already remarked that high excellence in one physical capacity seems correlated with decided superiority in all the others. This is evident from a glance at the tables. But it deserves notice that *equally* high excellence is not by any means implied. The chance of a man who is in one of these physical first classes being also in another such class is not very much more than what it would be if the two capacities were distributed at random. As a matter of fact, four men only out of the entire number are in every one of these first classes. As between the exertions of muscular strength apparently so closely similar as those of pulling and squeezing, it is found that only 44, out of the total of 195 in the latter, also secured a place in the former; whereas a purely chance distribution might have been expected to secure as many as about 20. As between the corresponding selections, of about equal numbers, from the best in respect of eyesight and breathing, it appears that not more than 30 obtain a place in both classes.

Turn now to some of the less obviously certain conclusions. Comparing the "head-volumes" of the students, two facts claim notice, viz. first, that the heads of the high-honour men are distinctly larger than those of the pass men; and, second, that the heads of all alike continue to grow for some years after the age of 19.

The actual amount of difference as between the A and C students is, of course, small. On our scale it is just about 7 inches—that is 3 per cent. on the real size of the head. Is this small difference to be regarded as significant? The answer can only be given by an appeal to the theory of statistics, which yields the following conclusions.

I must premise that the figures given here as average head-volumes were thus obtained. The average was taken of each of the three separate head-measurements (in the three directions

[1] See Mr. Galton's paper on this subject at the last meeting of the British Association.

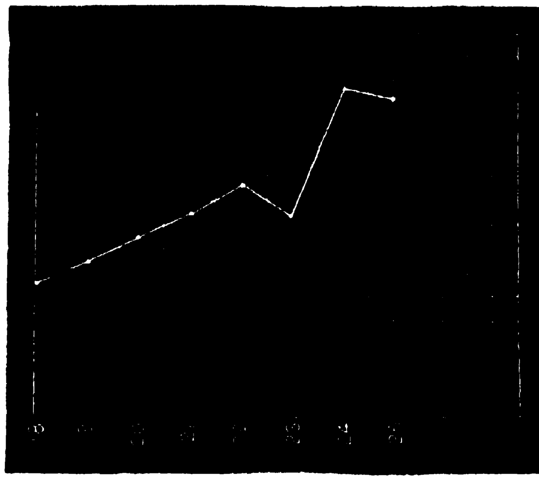
already explained) of each sub-class of students—*e.g.* of those of the A class who were 19 years of age; these three were then multiplied together, and the product resulting (in the case in question, 242·9) was entered in the table. What we have, therefore, is not strictly the mean of the products, but the product of the means. Theoretically, I apprehend, the former should have been preferred; but as the extra labour entailed would have been very great, and as the difference, when dealing with large numbers of cases and small amounts of divergence, is extremely small, I have been content with the latter. It may be added that the actual computation was made in both of these ways for a sample number of cases, and the insignificance of the difference for our purposes of comparison was statistically verified.

What theory directs us to do is of course to begin with determining the probable error of the individual head-volumes of the men generally. This is found to be, on the scale in question, about 17 inches. The usual formula for the difference between the means of 734 and of 487 would then assign to this difference a probable error of $17 \times \sqrt{\frac{1}{734} + \frac{1}{487}}$, viz. nearly one inch. The actual observed difference, of nearly 7 inches, thus lies enormously outside the bounds of probability of production from mere statistical chance arrangement. But in this calculation there is a source of error omitted to which attention was directed not long ago by a correspondent in NATURE, viz. the actual errors (in the literal sense of that rather unfortunate technical term) committed by the observer, or involved in the mechanism of the instrument. Two years ago I had taken it for granted that these were insignificant; and, had it been otherwise, the materials at our disposal would hardly have enabled us to make the due allowance. But, as the correspondent pointed out, the error is by no means to be neglected, and we have now the means of fairly estimating it. A considerable number of men have been measured five or six times, and some even oftener, whilst one man, who seems to have had a morbid love of this physical inspection, has actually had his various dimensions and capacities tested no less than eighteen times during the course of some three years. These cases have furnished a fair basis of determination. They show that these personal errors are certainly greater than they should be (they seem to arise in part from a certain looseness in the machine, which will be remedied in future), amounting in certain extreme cases to as much as even half an inch on the single measurement, and therefore to much more in what appears here as a "head-volume." The resultant "probable error" from this fresh source of disturbance amounts to about five (cubic) inches. Those unfamiliar with probability may perhaps be staggered by such an admission, but they may be assured that the healing tendency of the averages of large numbers is very great, and that the results remain substantially unaffected. The problem appears to be simply one of the superposition of two independent sources of error, and may be stated thus: Given a large number (over 2000) of magnitudes, with a mean of 239, and a "probable error," about this mean, of 17; and assume that these magnitudes are inaccurately measured with a further probable error of 5 inches (as seems to be the fact), what is the probable error of the divergence between the two averages obtained respectively from 734 and 487 of these results? The answer is still a little less than one inch. It is, that is to say, an even chance that the two averages will not differ by more than this; and it is, consequently, thousands to one that they will not differ by so much as seven inches. The conclusions, therefore, previously drawn, lose little of their force.

It seems to me almost as certain that the size of the head continues to increase up to at any rate the age of 24. This will be made clear by looking at the following diagram, which is drawn to show the sum of the figures of the head-measurements as contained in Table III.

As regards the comparative physical endowments, in the other respects, of the different classes of students, there does not seem to be much to say. The differences—sometimes one way and sometimes the other—between them in respect of height, weight, breathing, and squeezing power, are so small as to be statistically insignificant, averaging only about 1 per cent. That the first-class honour men, however, have slightly inferior eyesight seems established, especially when we bear in mind that each batch of about 1000 cases tells the same tale; the only evidence telling the other way is the fact, already adverted to, that when a class comprising "the best in ten," as regards eyesight, is selected from the whole number, we do not find any appreciable intellectual selection to be thereby entailed.

An equally trustworthy basis of comparison is found by observing the distribution of the short-sighted men. Let us take as the limit of what shall be termed "short sight" the inability to read the diamond print with both eyes at a distance greater than ten inches. Adopting this test, we find that the A, B, C classes furnish respectively 14, 11, and 11 per cent., indicating a very small difference between them.



The general conclusion to be drawn here seems, then, to be this. With the single exception of eyesight—and this to a very slight extent—it does not appear that intellectual superiority is in the slightest significant degree either correlated with any kind of natural physical superiority or inferiority, or that it tends incidentally to produce any *general* superiority or inferiority. I emphasize the word "general" in the last clause in order to allow for the difference shown in respect of pulling power. It seems probable, as has been already suggested, that the superiority of the non-honour men does not point to the slightest superiority of their general bodily development—as would be indicated perhaps if it displayed itself in respect of their height, weight, or breathing capacity—but is solely brought about by greater muscular exercise in the pursuit of certain athletic games.

So much as regards the first and second tables. As regards the third—which is arranged in order to show the development

TABLE III.

Physical Development of Students from 18 *to* 25.
A, B, C *combined* (2134).

of the physical powers between 18 and 25—there is very little to be said, as statistics of this character offer no particular novelty. Such merit, therefore, as this may possess must depend mainly on the homogeneity of the class of men concerned. As indicated at the commencement of this paper, this homogeneity is equivalent to a considerable increase in the total numbers where more heterogeneous materials are dealt with. They appear to indicate that the physical powers, as a whole, culminate at the age of 22 or 23, and thence begin to steadily decline. Too much stress, however, must not be laid upon the rate of decline here, since the last subdivision is of a somewhat less homogeneous character than the others. For one thing, the men of twenty-five really include those also who are *over* that age, though these are relatively but few. Again, whilst the men up to 24 remain (for all statistical purposes) identically the same individuals, with a year or two more added on to their

age, it would probably be found that a not insignificant proportion of those marked as 25 were men who were already older when they came into residence. J. VENN.

ABOUT eighteen months ago a brief memoir of mine—"Head Growth in Students at the University of Cambridge"—read before the Anthropological Institute, was published in NATURE (vol. xxxviii. p. 15). The *means* obtained by Dr. Venn, of the "head-products" of Cambridge students between the ages of nineteen and twenty-five were there thrown into the form of a diagram, and discussed. The head-product, I may again mention, is the maximum length of the head, × its maximum breadth, × its height above the plane that passes through the following three points: 1 and 2, the apertures of the ears; 3, the average of the heights of the lower edges of the two orbits. I drew curves that appeared to me to approximately represent the true average rate of growth, and deduced from them the following conclusions, in which I have now interpolated a few words in brackets, not because any criticism has been founded on their emission, but merely as a safeguard against the possibility of future misapprehension.

(1) Although it is pretty well ascertained that in the masses of the population the brain ceases to grow after the age of nineteen, or even earlier, it is by no means so with University students.

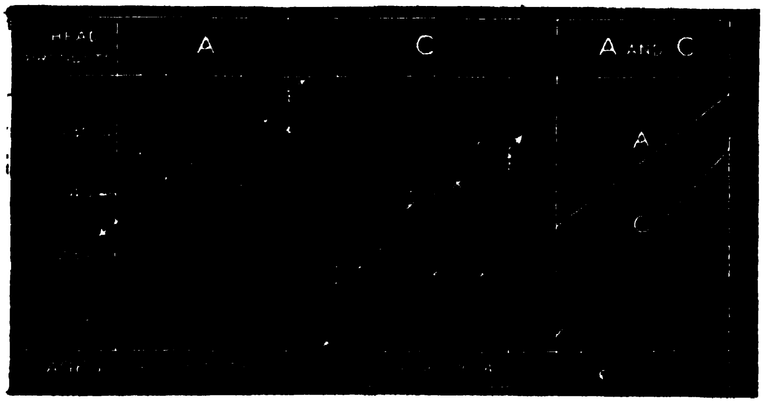
(2) That men who have obtained high honours have had [on the average] considerably larger brains than others at the age of nineteen.

(3) That they have [on the average] larger brains than others, but not to the same extent, at the age of twenty-five; in fact, their predominance is by that time diminished to [about] one-half of what it was.

(4) Consequently, "high honour" men are presumably, as a class, both more precocious and more gifted throughout than others. We must therefore look upon eminent University success as [largely due to] a fortunate combination of these two helpful conditions.

These conclusions have been latterly questioned by two of your correspondents, partly on the ground of discordance among the data, and partly on that of insufficient accuracy of the individual observations. To this I replied, that materials had since been accumulating, and that a second batch of observations, about equally numerous with those in the first, were nearly ripe for discussion, and that I thought it better to defer discussion until these had been dealt with; then, their agreement or disagreement with the first batch would go a long way towards settling the doubt.

This second batch of observations has now been discussed by Dr. Venn on exactly the same lines as the first one, and I give the results of both in the annexed diagram. The data from the



first batch, which formed the basis of the above-mentioned memoir, are here shown by dots with little circles round them; those from the second batch by crosses.

To the best of my judgment, the conclusions that were reached before are now confirmed. No person can, I think, doubt that the swarm of the A dots, and that of the C dots, are totally distinct in character. I have avoided drawing curves through either of them, lest by doing so the effect of the marks, when standing alone, should be overpowered, and it might be prejudiced. In their place, small arrow-heads are placed outside each diagram, to indicate the direction of the stretched thread that seemed most justly to represent the general trends of the two swarms of dots. Then, for the sake of convenient comparison, lines corresponding to these threads have been placed on the third diagram. It must, however, be understood that I have supposed the lines to be drawn straight, merely for convenience. In making my own final conclusions, I should take into account not only what the swarms of dots appear by themselves to show, but also the strong probability that the rate of head-growth diminishes in each successive year, and I should interpret the true meaning of the dots with that bias in my mind. FRANCIS GALTON.

SOCIETIES AND ACADEMIES.

LONDON.

Chemical Society, February 6.—Dr. W. J. Russell, F.R.S., in the chair.—The following papers were read:—Observations on nitrous anhydride and nitric peroxide, by Prof. Ramsay, F.R.S. The author recommends as the best method of preparing pure nitrogen peroxide that the deep blue-green liquid, supposed to be a mixture of this oxide with nitrous anhydride, which is obtained by condensing the products of the interaction of arsenious oxide and nitric acid, be added to a solution of nitric anhydride in nitric and phosphoric acids, prepared by adding phosphoric anhydride to well-cooled nitric acid; after agitating the mixture, the upper layer is decanted and distilled. He assumes that the two oxides interact according to the equation: $N_2O_3 + N_2O_5 = 2N_2O_4$. The melting-point of the peroxide was found to be $10^{\circ}\cdot14$, in agreement with Deville and Troost's statement. The depression of the freezing-point caused by one part of chloroform in 100 parts of the peroxide was $0^{\circ}\cdot35$, and by one part of chlorobenzene $0^{\circ}\cdot37$; the molecular depression is therefore 41°. The heat of fusion, W, of the peroxide, calculated from this number and the observed fusing-point, by Van't Hoff's formula $W = \frac{0\cdot02T^2}{t}$, where T is the freezing-point of the solvent in absolute degrees and t the molecular depression, is 33·7 cals.; a direct determination gave 32·3 cals. To determine the molecular weight of nitrous anhydride, a known quantity of nitric oxide was passed into the peroxide, and the depression of the freezing-point determined. Assuming that an amount of nitrous anhydride equivalent to the nitric oxide was formed, the results gave the values of 80·9, 92·7, and 81·0 against 74, the value corresponding with the formula N_2O_3. The author was unsuccessful in freezing nitrous anhydride even at -90° by means of liquefied nitrous oxide. It was found to be soluble in this liquid, and it was further observed that as evaporation took place nitric oxide gas was given off together with the nitrous oxide; it would therefore appear that N_2O_3 is unstable even at the very low temperature at which nitrous oxide is liquid. In the discussion which followed the reading of the paper, Mr. Pickering pointed out, with reference to Prof. Ramsay's determination of the heat of fusion of nitric peroxide, that observations on substances which exercise an appreciable influence on each other cannot safely be used in deducing the heat of fusion. Thus in the case of mixtures of water and sulphuric acid, solutions containing 29·5, 18·5, 8·6, 1·0, and 0·07 per cent. of acid, gave respectively the values 37·4, 58·3, 79·9, 74·9, and 56·3 as the heat of fusion of water, instead of 79·6. In reply to Mr. Wynne, who remarked that nitric oxide alone should interact with nitric anhydride in the way attributed to N_2O_3, Prof. Ramsay stated that he had not examined the action of nitric oxide on nitric anhydride.—Note on the law of the freezing-points of solutions, by Mr. S. U. Pickering.—The action of chromium oxychloride on nitrobenzene, by Messrs. G. G. Henderson and Mr. J. M. Campbell.—Studies on the constitution of the tri-derivatives of naphthalene; No. 1, The constitution of β-naphthol- and β-naphthylaminedisulphonic acids R. and G.; naphthalenemetadisulphonic acid, by Prof. H. E. Armstrong, F.R.S., and Mr. W. P. Wynne. After alluding to the great theoretical importance of a study of the tri-derivatives of naphthalene, the authors draw attention to the necessity of determining the constitution of those tri-derivatives which are employed technically in the manufacture of azo-dyes in order that the dependence of colour and tinctorial properties on structure may be determined; and especially is this the case, since all are not equally valuable—β-naphtholdisulphonic acid G. (Gelb), like Bayer's β-naphtholmonosulphonic acid, interacting but slowly

with diazo-salts, whilst the corresponding β-naphthylamine-disulphonic acid G, like the Badische modification of β-naphthylaminemonosulphonic acid, is incapable of forming azo-dyes with the majority of diazo-salts. The method adopted in this and the following papers consists firstly in displacing the NH_2 radicle by hydrogen by v. Baeyer's hydrazine method and determining the constitution of the resulting naphthalenedisulphonic acid, and secondly in substituting chlorine for the NH_2 radicle by Sandmeyer's method, and characterizing the resulting chloronaphthalene-disulphonic acid and the trichloronaphthalene derived from it by treatment with phosphorus pentachloride. β-naphthylamine-disulphonic acid R is in this way found to have the constitution [$NH_2 : SO_3H : SO_3H = 2 : 3 : 3'$ (for nomenclature, see NATURE, vol. xxxix. p. 598)], and β-naphthylaminedisulphonic acid G, the constitution [$NH_2 : SO_3H : SO_3H = 2 : 1' : 3'$]. From the latter acid by the hydrazine method naphthalenemeta-disulphonic acid, the fifth known naphthalenedisulphonic acid, has been prepared; this yields a disulphochloride melting at 137°, and 1 : 3-dichloronaphthalene melting at 61°·5. The further investigation of derivatives of this acid is expressly reserved by the authors. The results obtained in the case of the G acid make it evident that, as in the case of the Bayer β-naphthol-sulphonic acid [$OH : SO_3H = 2 : 1'$] and Badische β-naphthyl-aminesulphonic acid [$NH_2 : SO_3H = 2 : 1'$], the action of diazo-salts is either retarded or prevented by the "protecting influence" exercised by an α-1'-sulphonic group.—Studies on the constitution of the tri-derivatives of naphthalene; No. 2, α-amido-1 : 3'-naphthalenedisulphonic acid, by the same. The constitution of the acid known technically as α-naphthylamine-ϵ-disulphonic acid is found to be [$NH_2 : SO_3H : SO_3H = 1' : 1 : 3'$], a result agreeing with that arrived at by Bernthsen (*Ber. der. deut. chem. Gesellsch* .22, 3327).—Studies on the constitution of the tri-derivatives of naphthalene; No. 3, α-naphthylaminedisulphonic acid, Dahl, No. iii., The constitution of naphthol-yellow S., by the same. α-naphthylaminedisulphonic acid No. iii. of Dahl's patent (Germ. pat. No. 41,957), which when diazotised and warmed with nitric acid yields naphthol-yellow S., is found to have the constitution [$NH_2 : SO_3H : SO_3H = 1 : 4 : 2'$], whence it follows that naphthol-yellow S. has the constitution [$OH : NO_2 : NO_2 : SO_3H = 1 : 2 : 4 : 2'$]. The trichloronaphthalene prepared from the α-naphthylaminedisulphonic acid affords a remarkable case of dimorphism: it is sparingly soluble in hot alcohol from which it crystallizes in slender needles melting at 66°; if the melting-point be redetermined as soon as solidification has taken place, it is found to be 56°, but if determined after a longer interval, 66°, as in the first instance. The trichloronaphthalenes prepared by Cleve from nitro-1 : 3'-dichloronaphthalene (m.p. given as 65°), and by Widman from 1 : 4-dichloronaphthalene-β-sulphochloride (m.p. given as 56°) are found to be identical with this compound, and to behave in the same way on fusion.

Geological Society, February 21.—Annual General Meeting.—Dr. W. T. Blanford, F.R.S., President, in the chair.—After the reading of the reports of the Council and of the Library and Museum Committee for the year 1889, the President handed the Wollaston Medal to Prof. J. W. Judd, F.R.S., for transmission to Prof. W. Crawford Williamson, F.R.S.; the Murchison Medal to Prof. E. Hull, F.R.S.; the Lyell Medal to Prof. T. Rupert Jones, F.R.S.; the balance of the Wollaston Fund to Mr. W. A. E. Ussher; the balance of the Murchison Geological Fund to Mr. E. Wethered; the balance of the Lyell Geological Fund to Mr. C. Davies Sherborn; and a grant from the proceeds of the Barlow-Jameson Fund to Mr. W. Jerome Harrison.—The President then read his anniversary address, in which, after giving obituary notices of several Fellows, Foreign Members, and Foreign Correspondents deceased since the last annual meeting, including the Venerable Archdeacon Philpot (who was the senior Fellow of the Society, having joined it in 1821), Dr. H. von Dechen (the oldest Foreign Member, elected in 1827), Mr. Robert Damon, Mr. J. F. La Trobe Bateman, Mr. W. H. Bristow, Dr. John Percy, the Rev. J. E. Tenison Woods, Mr. Thomas Hawkins, Prof. F. A. von Quenstedt, Prof. Bellardi, Dr. Leo Lesquereux, and Dr. M. Neumayr, he referred briefly to the condition of the Society during the past twelve months, and to a few works on palæontological subjects published in the same period. He also mentioned the finding of coal *in situ* in a boring at Shakespear Cliff, and then proceeded with the main subject of his address—namely, the question of the permanence of continents and ocean-basins. After reviewing the evidence derived from the rocks of oceanic islands, and the absence of deep-sea deposits in continental strata of various ages, he proceeded to the points connected with the geographical distribution of animals and plants, and gave reasons for believing that Sclater's zoological regions, founded on passerine birds, were inapplicable to other groups of animals or plants, and that any evidence of continental permanence based on such regions was worthless. He also showed that both elevations and depressions exceeding 1000 fathoms had taken place in Tertiary times, and gave an account of the biological and geological facts in support of a former union between several lands now isolated, and especially between Africa and India *viâ* Madagascar, and between Africa and South America. From these and other considerations it was concluded that the theory of the permanence of ocean-basins, though probable, was not proved, and was certainly untenable to the extent to which it was accepted by some authors.—The ballot for the Council and Officers was taken, and the following were duly elected for the ensuing year:—President: A. Geikie, F.R.S. Vice-Presidents: Prof. T. G. Bonney, F.R.S., L. Fletcher, F.R.S., W. H. Hudleston, F.R.S., J. W. Hulke, F.R.S. Secretaries: H. Hicks, F.R.S., J. E. Marr. Foreign Secretary: Sir Warington W. Smyth, F.R.S. Treasurer: Prof. T. Wiltshire. Council: Prof. J. F. Blake, W. T. Blanford, F.R.S., Prof. T. G. Bonney, F.R.S., James Carter, John Evans, F.R.S., L. Fletcher, F.R.S., A. Geikie, F.R.S., Prof. A. H. Green, F.R.S., A. Harker, H. Hicks, F.R.S., Rev. Edwin Hill, W. H. Hudleston, F.R.S., J. W. Hulke, F.R.S., Major-General C. A. McMahon, J. E. Marr, H. W. Monckton, E. T. Newton, F. W. Rudler, Sir Warington W. Smyth, F.R.S., W. Topley, F.R.S., Rev. G. F. Whidborne, Prof. T. Wiltshire, H. Woodward, F.R.S.

PARIS.

Academy of Sciences, March 3.—M. Hermite in the chair.—On the absorption of atmospheric ammonia by soils, by M. Th. Schlœsing. Experiments were made on the quantities of ammonia absorbed in a given time by various soils—viz. non-calcareous earths, similar to those previously used in the fixation of free nitrogen, earths containing 40 per cent. of calcareous matter, and entirely calcareous earths. The analytical results are given for each case.—Contribution to the chemistry of the truffle, by M. Ad. Chatin.—Upon the method of using, and the theory of, seismographic apparatus; note by M. G. Lippmann. The theory of the deduction of the true movement of the soil from the apparent movement, as indicated by the instruments, is mathematically discussed. A general solution of the problem is given, and applied to some special cases.—An historical note on batteries with molten electrolytes, by M. Henri Becquerel. It is shown that M. Lucien Poincaré was not justified in claiming the invention of such batteries, as M. Jablochkoff, so long ago as 1877, proposed the combustion of carbon in the nitrates as a source of electricity; and still earlier, thirty-five years ago, M. A. C. Becquerel studied similar methods.—A facsimile atlas to illustrate the history of the earliest period of cartography, by M. A. E. Nordenskiöld.—Observations of the new minor planet, Luther (288) (Hamburg, February 24, 1890), made at the Paris Observatory (equatorial of eastern tower), by Mdlle. D. Klumpke.—On the transversal magnetization of magnetic conductors, by M. Paul Janet.—On the localization of interference fringes produced by Fresnel mirrors; note by M. Charles Fabry.—Researches upon the dispersion of aqueous solutions, by MM. Ph. Barbier and L. Roux. The authors find, for concentrated solutions, that, if B be the dispersive power and p the weight of anhydrous substance dissolved in unit of volume of the solution, the relation $B = Kp + b$ holds, b being always sensibly equal to the dispersive power of water. The specific dispersive power is practically a constant quantity for each substance.—On the vapour-density of the chlorides of selenium, by M. C. Chabrié.—Upon some derivatives of erythrite, by MM. E. Grimaux and Ch. Cloez. The writers, by investigating the transformations of hydrofurfural, have attempted to establish its constitution and the method whereby it is formed from erythrite. They conclude that hydrofurfurane may be represented by the formula $\left.\begin{array}{l} CH\,.\,CH_2 \\ \| \\ CH\,.\,CH_6 \end{array}\right\rangle O$.—Derivatives of hepta-methylene; note by M. Markownikoff.—Researches on the

preparation and properties of aricine, by MM. H. Moissan and Ed. Landrin.—Influence of light and of the leaves upon the development of the tubers of the potato, by M. Pagnoul.—The comparative physiology of the sensations of taste and touch; note by M. Raphael Dubois.—A method of studying the nuclei of white corpuscles, by M. Mayet.—On the localization, in plants, of the principles which yield hydrocyanic acid, by M. Léon Guignard.—On the intensification of sexuality in a hybrid (*Ophrys tenthrediniferoscolopax*), note by M. L. Trabut.—On the relations which appear to exist between the Cretaceous Mammalia of America and the Mammalia of the Cernaysienne fauna in the neighbourhood of Rheims.—Remarks by M. Albert Gaudry on the communication of M. Lemoine; appearances of inequality in the development of the beings of the Old and New Worlds.—New anthropological discoveries at Champigny (Seine), by M. Émile Rivière.—Note on the formation of the delta of the Neva, according to the latest researches, by M. Venukoff.

THURSDAY, MARCH 20, 1890.

A NATURALIST IN NORTH CELEBES.

A Naturalist in North Celebes. By Sydney J. Hickson, M.A. (Cant.), D.Sc. (Lond.), M.A. (Oxon. Hon.Caus.). With Maps and Illustrations. Pp. 392. (London John Murray, 1889.)

THIS book is the outcome of the residence of a specialist for nearly a year upon a small island off the extreme north point of Celebes. Of books of travel there is in these days no lack, and so beaten are the paths along which authors for the most part lead us, that the reader in search of amusement or instruction not infrequently arrives at the index without having met with either. But Dr. Hickson's is not a book of travel: it is a record of a naturalist's life with an almost boundless submarine field for observation close at hand—albeit terrestrially somewhat limited—and when he leaves his coral-girt island, it is to wander in that little-known archipelago which links Celebes to the Philippines, the Sangir, Nanusa, and Talaut groups, whither few but adventurous Dutchmen have penetrated.

Of the fourteen chapters, three are devoted to Talisse, the island on which Dr. Hickson conducted his observations. Four are descriptive of his wanderings in the groups just mentioned, and the remainder for the most part treat of the Minahassa district, its natives, and their mythology and customs. Of these, the author tells us in his preface that "the greater part of the ethnological portion of the book is borrowed from the valuable writings to be found in many of the reports of missionary and other societies, and in Dutch periodicals."

Dr. Hickson owing his voyage almost entirely to a desire to study the corals of the Malay Archipelago, it is naturally to that part of the book which treats of them that we first turn. No one has ever yet done justice to the wonderful beauties of coral-land, and the author, in common with his predecessors, has failed—as everyone must fail—to convey to the untravelled reader an adequate idea of the appearance of a vigorous reef. Perhaps the very fact of being an authority has lessened his chance of success. The description is nevertheless a good one, and the chapter (vi.) the most important in the book. Dr. Hickson has wisely relegated his technical work to the publications of the various learned societies, but he tells us much of interest. The first sight of a coral reef at close quarters astonished him—specialist as he was:—

> "I could not help gazing with wonder and admiration on the marvellous sight. . . . I had expected to see a wonderful variety of graceful shapes in the branching madrepores and the fan-like, feather-like alcyonarians, . . . but I was not prepared to find such brilliancy and variety of colour" (p. 15).

That vexed and most important question, the growth of coral reefs—a question upon which it was to be hoped that Dr. Hickson might be able, from the length of his stay and his varied opportunities, to enlighten us—is left pretty much where it was. We should be able to predict with certainty the direction and the rapidity of growth. As it is now, charts of coral islands and reefs become almost valueless in the course of a few years. But the causes both of growth and erosion are still undetermined. Much, no doubt, depends upon the rapidity of the tides. In strong tide-races no true coral reef is ever formed. "Flowing water, which is neither too swift nor too stagnant, bearing the kind of food necessary for the proper nourishment of the corals," is, as Dr. Hickson justly remarks, a strongly predisposing element to vigorous growth. Yet this is not always the case, neither does the converse always hold good; and we cannot agree entirely with the author when he says, "in deep bays or inlets, where tidal and ocean currents are scarcely felt, there is but little vigour in the reef." The inner harbour of Amboyna displays as rich a "sea garden," perhaps, as any in Malayan seas.

Dr. Hickson's daily work on the reefs led him to the certain conclusion that but one true species of *Tubipora* exists. The size of the tubes and the character of the septa—upon which most of the species are founded—are shown to be utterly without specific value; these differences depending entirely upon the position of the coral on the reefs. The following remarks upon a fact which must have struck most naturalists in tropic seas, but which we do not remember ever to have seen in print before, are worthy of quotation. Talking of sunrise and early morning, he says:—

> "Not only are the birds and insects, which disappear as the sun becomes more powerful, particularly visible at that hour, but it is the time of day above all others when the surface of the sea teems with animal life. I remember well my disappointment when I first got into tropical waters at finding that my surface-net invariably came up almost empty. It was not until I had been at work some time that I made the very simple discovery that in the early morning hours every sweep of the net brings up countless pelagic forms of all sizes and descriptions" (p. 58).

The question of the food of corals is yet unsettled; but the author, after careful examination of polypes of various kinds, is inclined to the belief that many of them may be, partially at least, vegetable feeders. No doubt the water n the vicinity of mangrove-swamps is very largely charged with the *débris* of leaves and fruit and wood, some of which, sinking to the bottom, must enter the mouths of the polypes. Upon the mesenterial filaments of the Alcyonarians, indeed, particles of vegetable fibre are frequently found. It is suggested that the vigorous reefs frequently seen near extensive swamps, may be explained by such an hypothesis. Upon Darwin's theory of the formation of atolls, Dr. Hickson had little opportunity of forming an opinion—little, at least, until he visited the archipelagos already mentioned. He ultimately came to a disbelief in the general subsidence theory, and is not opposed to Mr. Murray's view—that coral reefs can, under favourable circumstances, grow out into deep sea-water upon the talus of their own *débris*.

Among many references to birds occurs an account (p. 41) of the existence of the maleo, or brush-turkey, in Ruang Island. Unfortunately, we are not told whether this is *Megacephalon maleo*, or the smaller *Megapodius gilberti*. They were most probably the latter; but it would be interesting to know, for the true Megacephalon of Celebes has never, we believe, been recorded as

occurring in the smaller islands. Meyer's story of the whimbrels nesting on trees (probably *Numenius uropygialis*, Gould, by the way—not *N. phæopus*) is quoted, but without comment, and it is worthy of remark that no naturalist has as yet confirmed it. Dr. Hickson is not quite accurate in his statement that there are only two Celebean birds which are likewise English. He must often have noticed, in his rambles along shore, not only the common sandpiper, but also the wide-ranging *Strepsilas interpres* and one or more of the genus *Totanus*, which are not unfamiliar to us at home.

Perhaps one of the best passages in the book is that describing a mangrove-swamp, where the extraordinary conditions of life obtaining within its limits, and the interdependence of that tree and the coral reef, are well illustrated. The scenery of Talisse Island is not particularly beautiful, although the author does not tell us so; but that of the district of Minahassa on the mainland is strikingly lovely, and he describes the view of the Tondano Lake as one without an equal. It was unspoilt to him even by the thought of the "*heerendienst*"—that system of compulsory service which has acted as a red rag to so many Englishmen. Dr. Hickson is not so prejudiced, and is wise enough to recognize—as did Wallace—the enormous advantage which it has conferred upon the people.

"I cannot help thinking," he says (p. 208), "that everyone who is really acquainted with the circumstances of these colonies and the character and condition of the people must admit that it is a service both necessary and just. The Dutch Government has brought to the people of Minahassa not only the blessings of peace and security, but also the possibilities of a very considerable civilization and commercial prosperity. . . . In return for all this, it is only just that every able-bodied man should be compelled to lend a hand in maintaining this happy condition of affairs. In a land where the necessities of life are so easily obtained, . . . it would be impossible for the Government to obtain a sufficient number of them to labour on the roads at a reasonable wage."

The consequence is that they would be neglected. The *heerendienst*, then, as Dr. Hickson shows, is the only system possible, without overburdening the Exchequer, or increasing the taxation beyond the endurance of the people.

We have not space to dwell upon the description of the Sangir Islands, or on the mythology and customs of the natives of Minahassa, which Dr. Hickson has done well to put within the grasp of those who are unacquainted with the Dutch language. Among the folk-lore it is interesting to notice (p. 241) the story of Lumimuüt's impregnation by the west wind—a story which, if we mistake not, is almost identical with one of Egyptian source. The "swan-maiden" tale—which, perhaps, has as wide a distribution over the surface of the globe as any other—again occurs in Celebes. Enough has been said to show that "a naturalist in North Celebes" had a varied interest in his surroundings, which he has contrived to communicate to his readers with success. A little more care, perhaps, would have purged the volume of several misprints, and one or two instances of involved diction.

The woodcuts with which the book is furnished are well enough. We wish that anything could be said in favour of the "process" illustrations. That at p. 33 is bad, and another at p. 137 still worse. But anything more muddy and meaningless than that facing p. 45 we confess never to have seen.

F. H. H. GUILLEMARD.

SAINT-VENANT'S ELASTICAL RESEARCHES.

The Elastical Researches of Barré de Saint-Venant. (Extract from Vol. II. of Todhunter's "History of the Theory of Elasticity.") Edited, for the Syndics of the University Press, by Karl Pearson, M.A., Professor of Applied Mathematics, University College, London. (Cambridge: At the University Press. London: C. J. Clay and Sons. 1889.)

OUR fears lest this "History of the Theory of Elasticity" should, like Thomson and Tait's "Natural Philosophy," remain a magnificent mathematical torso have been agreeably falsified by the early appearance of this instalment of the second volume. It is devoted entirely to the work of Saint-Venant, the distinguished French mathematical engineer.

Saint-Venant is one of the rare examples of a writer who is equally popular with the mere mathematician and with the practical engineer. To quote from the author's preface to this part of the "History of Elasticity," "we live in an age when the physicist awaits with not unreasonable excitement for greater revelations than even those of the past two years about the ether and its atomic offspring; but we live also in an age when the engineer is making huge practical experiments in elasticity, and when true theory is becoming an absolute necessity for him, if his experiments are to be of practical as well as of theoretical value." This is the opinion of the theorist; but the engineer points to his work as magnificent experiments on a gigantic scale, to which he invites the theorist to an inspection, for him to deduce his theoretical laws.

So far as pure theory is concerned, the engineer trusts only to Hooke's law, and Euler's theory of the beam, which neglects the warping of the cross-sections. But Hooke's law is shown by the testing-machine to be only a working hypothesis within very narrow limits of extension and compression, after which the baffling phenomena of plasticity make their appearance, and destroy all the simple mathematical harmony; while as to Euler's theory of the flexure of the beam, the editor, Prof. Pearson, is at present engaged on the mathematical discussion of the permissible limits of the application of the ordinary theory, and, so far, the result of his investigations (in the *Quarterly Journal of Mathematics*) is such as to strike dismay in the heart of the practical man who would be willing to apply his conclusions.

The purely mathematical theory of Elasticity is, at the present moment, in a very curious condition, for a subject in the exact science *par excellence*. Not only are elasticians divided into opposite camps of *multi-constancy* and *rari-constancy*, but we find a war of opinion raging among the most recent investigators—Lord Rayleigh, Chree, Love, Basset, and others. All are compelled to violate apparently the most fundamental rule of mathematical approximation; and, in considering the elasticity of a

curved plate, to begin by neglecting the terms depending on the stretching of the material, which involve the first power of the thickness of the plate, in comparison with the terms depending on the bending, involving the cube of the thickness; thus apparently neglecting the first power compared with the third power of small quantities. But, if we take a thin sheet of brass or iron in our hands, we shall find it quite easy to bend, but apparently impossible to stretch or shear in its own plane, showing that the stretching stresses may be considered as non-existent, by reason of requiring such large forces to produce them.

Before pure mathematical treatment can make much progress in Elasticity, much more experimental demonstration is required of the behaviour of pieces of metal of mathematical form under given applied forces; and such experiments can be carried out in testing-machines, now forming an indispensable part of a physical laboratory.

Saint-Venant's memoir on torsion, analysed in Section I., is familiar to us through its incorporation by Thomson and Tait, and shows that Saint-Venant carried out, with the comparatively crude methods at his disposal, valuable experiments, from which much theoretical deduction has been made; the analogues of the mathematical analysis in the problem of the torsion of the cylindrical beam of given cross section, and of the flow of viscous liquid through a pipe of the same section, or of the rotational motion of a frictionless liquid filling the cylinder being very striking. Prof. Pearson introduces great elegance and interest into the series which arise by a free use of the notation of hyperbolic functions, and we think there is still some interesting work for pure mathematicians in the identification of those series which are expressible by elliptic functions. But it certainly looks curious to find in § [287] the old familiar polar co-ordinates treated as mere conjugate functions, without reference to their geometrical interpretation.

Section II. is occupied with the analysis of Saint-Venant's memoirs of 1854 to 1864, in which he attacks such questions in practical elasticity as the longitudinal impact of bars, illustrated by very ingenious graphic diagrams, and also the conditions of stress of a cylindrical shell, in equilibrium under given applied internal and external pressures. This is the problem required in the scientific design of modern built-up artillery; and it is noticeable that Saint-Venant's solution differs materially from Lamé's, subsequently popularized by Rankine, the theory employed, as far as it will go, by scientific gun-designers all over the world.

The researches in technical Elasticity of Section III. arose in the annotations of Navier's "Leçons sur la Résistance des Corps solides"; the mantle of Navier descended on the shoulders of Saint-Venant, and ultimately the notes of Saint-Venant overwhelmed the original text of his master Navier; and, according to Section IV., Saint-Venant has practically done the same thing with Clebsch's "Elasticität."

Being the mathematical referee for all the difficult theoretical problems arising with the extensive use of the new materials iron and steel in architecture and engineering, Saint-Venant was provided with a number of useful problems on which to exercise his ingenuity; such as the impact of bars, the flexure of beams due to a falling weight or a travelling load, the critically dangerous speeds of fly-wheels and piston-rods, and so on; all problems hitherto solved by practical rule of thumb, the practical constructor encountering and opposing the difficulties without knowing why and how they arose.

Saint-Venant's investigations urgently need extension and application to the critically dangerous conditions which can arise in the stresses in artillery, when the dynamical phenomena are analysed, due to the sudden and periodic application of the powder pressure, and to the wave-like propagation and reflection of the stresses in the material. At present, we can only investigate the theoretical strain set up in the material of the gun by a steady hydrostatic pressure equal to the maximum pressure of the powder, employing Lamé's formulas, and then employ an arbitrary factor of safety, say 10, in the design of the gun, to provide against the contingencies of the dynamical phenomena we have not yet learnt how to discuss.

In the old times, before the Cambridge Mathematical Tripos was reduced to its present meagre curriculum, the examiner would have found the present volume very useful in suggesting good ideas, capable of testing reasonably the mathematical power of the candidates; at present, the chief class to profit by the present work are the practical constructors, who will learn where to look for the useful information on the narrow technical point which concerns them.

Prof. Pearson has brought his onerous task one step nearer to completion in this interesting volume, a monument of painstaking energy and enthusiasm.

A. G. GREENHILL.

GLOBES.

Hues's Treatise on the Globes (1592). Edited by Clements R. Markham, C.B., F.R.S. (London: Reprinted by the Hakluyt Society, 1889.)

THE Hakluyt Society has for its object the reprinting of rare or unpublished voyages and travels, and few are worthier of this honour than the "Tractatus de Globis" of Robert Hues. The author of this work was an intimate friend of Sir Walter Raleigh, and combined book-learning with practical knowledge gained by joining in some of the voyages to the New World with navigators whose names have made the sixteenth century famous. He strongly urged that his countrymen would have still further surpassed their Spanish and Portuguese rivals if they had "but taken along with them a very reasonable competency and skill in geometry and astronomy." In those days logarithms were unknown, and the solution of the problems of nautical astronomy required advanced mathematical knowledge. It was hoped that this difficulty would be overcome by the extended use of globes, which at once reduces these complex questions to approximate solution by inspection. After the construction of the Molyneux globes, Hues's treatise came into very general use, and no doubt played an important part in the explorations of the succeeding century.

It seems strange in these days, when a globe can be purchased for a few shillings, to read that only three centuries ago the construction of globes entailed such great expense that the liberal patronage of a merchant

prince was required before such an undertaking could be entered upon. Readers of Kingsley's masterpiece will not need to be reminded that the funds were supplied by "Alderman Sanderson, the great geographer and setter forth of globes." Emery Molyneux, a mathematician of whom little is known, was entrusted with the construction of the globes, but although several were manufactured and sold, only one set has been preserved, and this has found a strange resting-place in the library of the Middle Temple.

From the admirable introduction by the editor, we learn that the celestial preceded the terrestrial globe by many centuries. It has been asserted that Atlas, of Libya, discovered the use of the globe, and thus gave origin to the fable of his bearing up the heavens on his shoulders. There are several allusions to globes by the ancient writers, and on the medallion of the Emperor Commodus a celestial globe is clearly represented. None of the Greek or Roman globes, however, have been preserved. Amongst the oldest in existence are those made by the Arabian astronomers, dating from the thirteenth century. These are made of metal, on which the stars are engraved, and five of them are still with us, one belonging to the Royal Astronomical Society. The oldest globe, now at Florence, was constructed in 1070; and, though it is only 7·8 inches in diameter, 1015 stars are engraved upon it.

The terrestrial globe apparently dates from 1492. Baron Nordenskiöld points out that this is the first adoption of the notion of antipodes, and the first to show a sea-passage from Europe to India. The first map on which the name of America appears was found amongst the papers of Leonardo da Vinci at Windsor Castle; it is drawn on eight gores, and was probably intended for a globe. The next terrestrial globe of interest was that completed by Mercator in 1541, having a diameter of 16 inches. Others succeeded, and finally we come to the enlarged and improved globes constructed by Molyneux. These are twenty-six inches in diameter, and differ little in construction from our modern globes, but the geography, of course, differs very considerably.

The original work of Hues was in Latin, and went through several editions. Nine editions in Dutch and French followed, the most important being the Dutch one annotated by Isaac Pontanus. The latter was translated into English by John Chilmead in 1638.

The treatise is divided into five parts, the first dealing with things common to both globes, the second with planets and stars, the third with the geography of the terrestrial globe, the fourth with the use of the globes for purposes of navigation, and the fifth is a treatise on the use of rhumb lines, by Thomas Herriot. The book is especially interesting on account of the many references to the theories of the ancients and contemporaries, the whole forming a valuable history. The discussions of the size and shape of the earth are particularly striking. After giving the diverse opinions as to the length of a degree, the measures varying from 480 to 700 furlongs, the author concludes with the remark: "Let it be free for every man to follow whomsoever he please."

A geographical index at the end gives a long list of places, with their latitudes and longitudes, which has been reprinted with the hope that it may be of use in identifying old names. Longitudes in those days were measured from a point in the Azores, London thus having a longitude of about 26°.

Two other indices have been added, one a biographical index, and the other an index to the names of stars and constellations. Both of these are very complete, and will be of great interest to those wishing to learn a little about ancient astronomers and the origins of astronomical names.

A. F.

THE PSYCHOLOGY OF ATTENTION.

The Psychology of Attention. By Th. Ribot. Authorized Translation. (Chicago: The Open Court Publishing Company, 1890.)

IN this neat little volume of little more than a hundred pages we have a very careful and lucid consideration of *attention* from the standpoint of scientific psychology. Adopting the division of attention into two well-defined forms—the one spontaneous or natural (non-voluntary or reflex of Mr. Sully's "Outlines"), the other voluntary or artificial—Prof. Ribot devotes his first chapter to the former and his second to the latter. In a third he deals with "morbid forms of attention." These, with a short introduction and a short conclusion, constitute the compact little work. Although there is not very much that is, strictly speaking, new—and is this to be expected?—there is scarcely a page without some apt illustration, some pithy epigram, or some well-expressed generalization. It is a closely-reasoned and luminous exposition of a genuine piece of psychological work.

The four points on which the author lays most stress are the following:—(1) Attention is caused by, or has its origin in, emotional states. (2) Under both its spontaneous and voluntary manifestations it is, "from its origin on, bound up in motory conditions." (3) Intellectually it is a state of relatively perfect monoideism. (4) It has a biological value. Of these, the second is the most essential. The motor element in attention is the keynote of the whole argument. The emotions from which we start are not merely complexes of pleasurable or painful elements floating free in a purely mental atmosphere. They are the psychological accompaniments of certain activities or tendencies to activity. The pleasure and pain associated with these activities are "the hands of the clock, not its works"—or, to change the analogy, "they follow tendency as the shadow follows the body."

And as the motor element is present at the emotional initiation of attention so too is it present through every phase of its existence. The motor effect may, however, be manifested under either of two forms: it may be impulsive and produce movement; or it may be inhibitory and withhold movement. Attention accordingly means the concentration or the inhibition of movements; while its converse, distraction, means diffusion of movements. Steadily applied work is the concrete, the most manifest form of impulsive attention; steadily applied thought the ultimate goal of inhibitive attention; for, as Prof. Bain has well said, "To think is to refrain from speaking or acting." Such movements as are still requisite for continued life, such as those of respiration, are under strict control. The master-idea, so far as is

possible, drains for its own use the entire cerebral activity.

Attention from the first has had a biological value.

"Any animal so organized that the impressions of the external world were all of equal significance to it, in whose consciousness all impressions stood upon the same level, without any single one predominating or inducing an appropriate motory adaptation, were exceedingly ill-equipped for its own preservation."

Attention has thus been a factor in the progress of life, or, as Prof. Ribot puts it epigrammatically, attention is a condition of life. In the lower animals, under normal conditions, attention is for the most part spontaneous; or, to use the author's alternative term, natural. One may perhaps say that in natural or spontaneous attention the motive or interest is inherent, while in voluntary or artificial attention it is extraneous. And the process by which voluntary attention is developed is by rendering attractive by artifice what is not attractive by nature; by giving an artificial interest to things that have not a natural interest. This, too, is a factor in progress; this, too, has a biological value.

"In the course of man's development from the savage state, so soon as (through whatever actual causes, such as lack of game, density of population, sterility of soil, or more warlike neighbouring tribes) there was only left the alternative of perishing or of accommodating oneself to more complex conditions of life—in other words, going to work—voluntary attention became a foremost factor in this new form of the struggle for existence. So soon as man had become capable of devoting himself to any task that possessed no immediate attraction, but accepted as only means of livelihood, voluntary attention put in an appearance in the world. It originated, accordingly, under the pressure of necessity, and of the education imparted by things external."

We have thought it more just to our author, and more satisfactory to our readers, to give some account of Prof. Ribot's main theses with which we are in full sympathy, than to select minor points, of which there are but few, in which we differ from his conclusions. The translation is, on the whole, satisfactory, but some expressions, such as "the marrow and the bulb" (for the spinal cord and medulla), "moderatory centres," and "the fundament of emotional life rests in tendencies," &c., strike one as somewhat unusual. C. Ll. M.

OUR BOOK SHELF.

Handleiding tot de Kennis der Flora van Nederlandsch Indië: Beschrijving van de Families en Geslachten der Nederl. Indische Phanerogamen. Door Dr. J. G. Boerlage. Eerste Deel, Eerste Stuk. "Ranunculaceæ—Moringaceæ." Pp. 312. With an Index. ("Introduction to a Knowledge of the Flora of the Dutch East Indies." (Leyden: E. J. Brill, 1890.)

THIS is the first part of a work consisting of descriptions of the natural orders and genera of flowering plants represented in the Dutch East Indies. A work thus limited must necessarily be of limited utility; but we have Dr. Treub's testimony in a preface thereto that he regards it as a highly useful forerunner of a new Flora of the country. It is nearly five-and-thirty years since Miquel began publishing his "Flora," and the last part of it appeared in 1860, before Bentham and Hooker's "Genera Plantarum" commenced; and systematic botany generally has experienced extraordinary development since then. Further, one of the great advantages claimed for the present work is that it is wholly in Dutch. It is based on Bentham and Hooker's "Genera Plantarum," and we find on comparison that the ordinal, tribual, and generic definitions are to a great extent translations, though later additions to the flora, both in genera and species, have not been neglected. Dr. Boerlage's book will also be useful to the phytographer, as it is already something to have a synopsis of the genera found in the large eastern area under Dutch dominion. Geographically, the next descriptive "Flora" of the region should include the whole of "India aquosa," which means, at least, an examination of the plants of the whole of tropical Asia, of tropical Australia, and of Polynesia. Such a work, on lines similar to Hooker's "Flora of British India," would be of immense value; but it requires qualified men, with sufficient time, money, and ample materials from the whole area. W. B. H.

The Elements of Laboratory Work. By A. G. Earl, M.A., F.C.S. (London: Longmans, Green, and Co., 1890.)

THIS volume is of such a character that the reader is at once tempted to seek for its excellences rather than for its weak points. It aims at presenting "an introduction to all branches of natural science," and is intended to be used as a hand-book in the laboratories of public schools that have well-equipped rooms devoted to practical science. The author says in his preface that such rooms "are now-adays considered a necessary part of all public schools and colleges." Granting that this is the case, that the teacher is good, and that his pupils are already highly trained and anxious to learn pure science for its own sake, this volume might be accepted as an excellent guide. It is marked by a total absence of the "familiar examples" which we have hitherto associated with elementary scientific works. The student is made to accustom himself to technical language from the very first. For example, "a set of *weights*," is, on p. 2, explained as being "a number of bodies so arranged," &c.; and a few paragraphs further on the student is directed to "verify the graduation of a burette," and is introduced to reading telescopes and cathetometers. The first introduction of the student to chemical changes is an experiment consisting of the ignition of silver nitrate with quantitative observations, the second experiment is similar but with silver iodate, and the third is the heating of silver nitrate in a closed tube over a small Bunsen flame. In an explanation of the significance of what are commonly known as atomic weights and molecular weights, the expressions atomic masses and molecular masses are used. We do not see the advantage of this novel nomenclature. If the volume had an index, we should be prepared to recommend it in unqualified terms for the use of school-boys who can carry out such instructions as the following: "Perform experiments illustrating the law that chemical combination takes place between definite quantities of different kinds of matter."

Magnetism and Electricity. Part II. Voltaic Electricity. By Prof. Jamieson, M.Inst.C.E., &c. (London: Griffin and Co., 1890.)

IF the third part of this work prove equal in excellence to the two already published, Prof. Jamieson may claim to have produced one of the best introductory text-books on the subject. Like its predecessor, Part II. treats the subject in an essentially practical way. A competent electrician himself, the author is well able to understand the difficulties which beginners are likely to meet with, and his attempts to make obscure things clear will probably be found highly successful. The theoretical side of the subject is carefully considered, and no important application of a principle is passed over without reference.

Instruments in actual use for what have now become every-day purposes are fully illustrated and described.

The book is well up to date both in the experimenta and applied branches. Mr. Shelford Bidwell's apparatus for studying the changes in length of a bar during magnetization is described in such a way as to make the object of the experiment and the method of carrying it out easily understood. More of this kind of thing in our text-books is very desirable as showing that progress in a science is not made by chance, but is the outcome of careful thought on the part of patient investigators.

As a text-book for classes where experimental work is encouraged it is especially suitable, but we recommend it to the notice of all beginners. Numerous questions and specimen answers follow the various chapters, and an appendix gives instructions for making simple apparatus.

Astronomy with an Opera-Glass. By Garrett P. Serviss. (London and New York: D. Appleton and Co., 1889.)

WE are glad to welcome this, the second edition of a popular introduction to the study of the heavens. The author has surveyed, with the simplest of optical instruments, all the constellations visible in the latitude of New York, and carefully noted everything that seemed of interest to amateur star-gazers. In addition to the map and directions given to facilitate the recognition of the constellations and the principal stars visible to the naked eye, many facts are stated concerning the objects described which render the work a compendium of useful and interesting information—an astronomical text-book as well as a star-atlas. Similar combinations are very desirable introductions to every science, and offer the best means of extending true knowledge. To lead the student to Nature, and direct his attention to some of her marvellous works, to make him see natural phenomena intellectually, should be the basis of all scientific instruction, and works constructed on these lines read like story-books. With such works the one before us should be included, and there could hardly be a more pleasant road to astronomical knowledge than it affords; replete with information, elegant in design, easy of reading, and practical throughout, it deserves to rank high among similar guides to celestial phenomena. A child may understand the text, which reads more like a collection of anecdotes than anything else, but this does not mar its scientific value, and if the work multiplies the number of observers, as it is calculated to do, the dearest wish of every astronomer will be gratified.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electrical Radiation from Conducting Spheres, an Electric Eye, and a Suggestion regarding Vision.

I DO not know how far the description of little isolated experiments is serviceable, but I am tempted to communicate a simple plan I use for exciting electric oscillations in dumb-bells, ellipsoids, elliptical plates, spheres, or other conducting bodies of definite geometrical shape unhampered by a bisecting spark-gap. I do it by supplying electricity to opposite ends of the conductor by means of Leyden jar knobs brought near enough to spark to it: said knobs being likewise connected with the terminals of a small Ruhmkorff coil. The charge thus supplied or withdrawn at every spark settles down in the conductor after a few oscillations, and these excite radiation in surrounding space.

There are many ways of arranging the Leyden jars: some more effective than others. The outer coats of the two jars may or may not be connected together. Connecting them in some cases brightens the sparks at short range, but seems to have a tendency to weaken them at long ranges. It is not difficult to surmise why this is so.

Of course, when the outer coats are disconnected, only an insignificant portion of the capacity of the jars is utilized; but unless the thing to be charged has too large a capacity it works perfectly well.

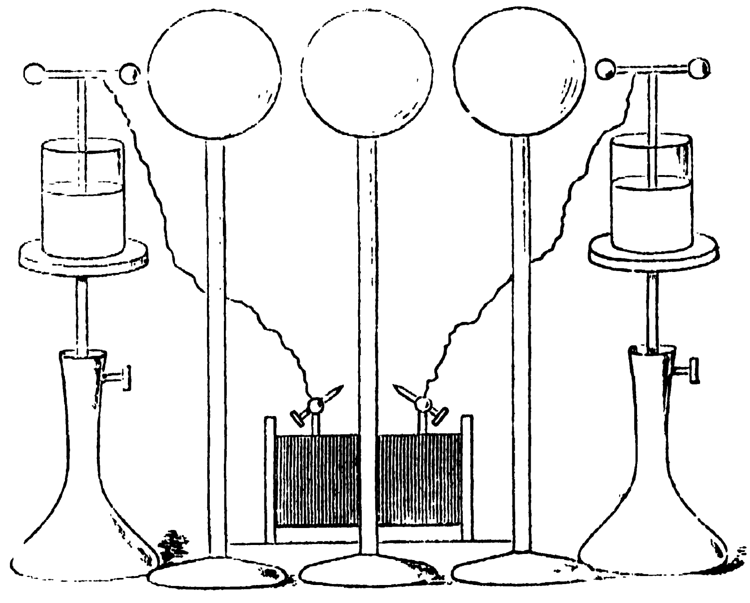
The receiver or detector is a precisely similar conductor touched to earth by a point held in the hand. The distance at which such a receiver responds is surprising. Or one may use a pair of similar conductors and let them spark into each other; but this plan is hardly so sensitive, and is more trouble.

The fact of being able in actual practice to get radiation from a sphere, is interesting, inasmuch as the subject of electrical oscillations in a perfectly conducting sphere has been worked out accurately by Prof. J. J. Thomson in the London Mathematical Society's Proceedings. I have not the volume by me, but I think he reckons the period of oscillation as the time required by light to travel 1·41 diameters of the sphere.

The case of spheres of ordinary metal will not be essentially different, with these rapid oscillations, for the electric currents keep to a mere shell of surface in either case; and in so far as *damping* affects the period, the dissipation of energy by radiation (which is common to both) is far greater than that caused by generation of heat in the skin of a metal sphere.

I happen to have four similar spheres of nickel-plated metal on tall insulating stems; each sphere 12·1 centimetres in diameter. Applying spark knobs to each end of a diameter of one of them, and applying the point of a penknife to another one standing on the same table at a distance of two and a half metres, I am able to get little sparks from it without using any reflector or intensifier.

Or arranging three spheres in a row, with intervals between and knobs outside, 5 short spark-gaps in all (see figure), and



using a fourth sphere as detector of this triple-sourced radiation, I draw little sparks from it to a touching penknife at a distance of 12 feet (366 centimetres, actual measurement).

In this case it may be a trifle better to hold one's hand near the receiving sphere at the side opposite to the penknife, and thus vary its capacity by trial so as to imitate the disturbing effect of the contiguous spheres in the transmitter.

The complete waves thus experimented on and detected are only 17 centimetres (six and a half inches) long, and I imagine are about the shortest yet dealt with.

But we do not seem near the limit set by lack of absolute suddenness in sparks yet, and are going on to try a large number of little globes.

Exciting a lot of little spheres by a coil in this way forcibly recalls to mind the excitation of a phosphorescent substance by a coil discharge.

And a receiver not very unlike the rod-and-cone structure of the retina can likewise be made. My assistant has been experimenting on a sort of gradated receiver which he made himself. I have recently had made a series of long cylinders with diameters ranging above and below 12 centims.; and the

length of each which responds to radiation is a kind of measure of specific intensity. They form (speaking sensationally) an electric eye with a definite range of colour sensation. It would be easy to supply it with a pitch or paraffin lens.

There is no need to suppose the retinal bodies to be conducting: a body of high refractive index should be subject to electric vibrations, and its surface to spurious electrifications, when radiation falls upon it; and the optical density of the rods and cones is known to be high. They may, however, be electrolytic conductors; and I find that a liquid sphere—*e.g.* a flask of inky water—responds to radiation, giving a glow to a point touching its glass.

The diameters of the rods, as measured by various physiologists, are not very different from dimensions adapted to respond to actual light-vibration frequency; and if this idea substantiates itself, these bodies can be supposed to constitute a sort of Corti's organ responding to etherial instead of to aërial vibrations, and stimulating in some still unknown, but possibly mechanical, manner, the nerve-fibre and ganglion with which each appears to be associated. University College, Liverpool, March 11.

"Peculiar Ice-forms."

MAY I add another to the long series of communications which from time to time have been addressed to you under the above heading? Most of them have described and discussed the occurrence of ice in the form of filaments. One signed by J. D. Paul (NATURE, vol. xxxi. p. 264) seems (the description is somewhat vague) to refer to a mode of ice formation which is of somewhat frequent occurrence here, and is the only reference to this mode which I can find in that portion of the literature of physics which is accessible to me.

It happens now and again in our variable climate that a loose porous soil which has been thoroughly soaked with rain is made by a sudden and a sharp frost to produce a crop of little columns of ice. I observed a striking instance lately on a piece of hard compact ground, which, not being quite smooth, had been covered with an inch or so of loose pebbly soil for levelling purposes. Before the loose soil had been rolled or trampled upon, it became saturated with water through two days of continuous rain; and while it was still saturated, a sharp frost set in at night. In the morning the ground, to the extent of 60 square yards, was found to be covered with little columns of ice, some of them about two inches in length. They were roughly circular in section; and each column had approximately the same section throughout. Their diameters ranged from one-tenth to one-third of an inch. They were not transparent, but were whitish in appearance, and carried on their summits pebbles or frozen earth. They were thus obviously not ice crystals, such as Brewster describes in the *Edinburgh Journal of Science*, vol. ix. p. 122, as occurring in similar circumstances. The columns started from the ground at various inclinations to the vertical, and in the great majority of cases they curved upwards to a greater or less extent. I had never noticed this upward curving of the ice columns before, but other persons familiar with the phenomenon assure me they have observed it.

The explanation of this mode of ice formation seems pretty obvious. The sudden frost solidifies the crust of the soil; and it may therefore sometimes happen (in the above case it clearly must happen) that water becomes imprisoned between the frozen crust and the impervious sub-soil. Further freezing enables nature to perform Major Williams's experiment for us. If the crust does not give way as a whole, it must at its weak points; and the internal pressure is relieved by the protrusion of ice columns through apertures formed at these points. These columns would naturally carry portions of the crust on their summits, and during their protrusion might be expected to have innumerable minute fissures or cracks produced in them so as to exhibit a whitish snowy appearance. At the base of any column, at points where the freezing-point has been lowered by the pressure to the actual temperature, melting is continually occurring, and the water thus formed will flow into the fissures referred to. If the axis of the column is inclined to the vertical, and if we assume that the fissures and the points at which melting occurs are pretty uniformly distributed, more water will flow into the fissures of the lower side of the column than into those of the upper side. When the water re-freezes therefore, the lower side must elongate more than the upper, and the column must consequently in general curve upwards. That in exceptional cases the upward curving may not occur is obvious.

On a Certain Theory of Elastic After-Strain.

IN a recent paper (Proc. Lond. Math. Soc., April 11, 1889), Prof. Karl Pearson has discussed at some length the possible forms of the additional terms which may be introduced into the general equations of elasticity by a consideration of the mutual action of the molecules and the ether, and has examined what physical phenomena may admit of explanation in this way. In particular, certain terms which thus appear admissible are made to yield a theory of the phenomenon known as "*elastische Nachwirkung*," or "after-strain." The attempt to explain such a comparatively slow process by the intervention of the ether certainly invites scrutiny, and in fact a very slight examination serves, I think, to show that the theory in question rests on a mistake. The author, after writing down the equations which (on his view) represent the steady application of stress to a portion of matter, proceeds to integrate them in the usual way by assuming a time-factor e^{mt}, and arrives at a quadratic in m^2 whose roots are μ/μ' and $(3\lambda + 2\mu)/(3\lambda' + 2\mu')$, where λ, μ are the ordinary elastic constants of Lamé, and λ', μ' are the coefficients of the additional terms referred to. He continues:—"Now m cannot be *positive*, so long at least as we are dealing with elastic-strain. For λ' and μ' are small as compared with λ and μ, the effects we are considering being only of the second order. Hence m^2 is large, and if m were positive the strain would rapidly grow immensely large, which is contrary to experience. Thus, we must give m the negative values $-\sqrt{(\mu/\mu')}$ and $-\sqrt{\{(3\lambda + 2\mu)/(3\lambda' + 2\mu')\}}$." The positive values of m are certainly inconvenient, but they are on the same footing with the negative ones; all are solutions of the author's equations, and all are required for the purpose of satisfying arbitrary initial conditions. The proper inference is surely that the substance is unstable, so long as the constants μ/μ' and $3\lambda' + 2\mu'$ are (as the author has tacitly assumed them to be) positive. If, to avoid this disaster, we change the signs of these constants, we get circular instead of exponential functions, and all analogy to elastic after-strain of course disappears. In its place we have *vibrations* (not molecular, but "molar") whose period is intrinsic to the substance and independent of the dimensions of the portion considered. To what physical reality these may correspond I do not undertake to say. HORACE LAMB.

Foreign Substances attached to Crabs.

IF, as Mr. Garstang seems to suppose, the presence of tunicates on a crab is to be regarded as a danger-signal to its enemies, then *Hyas* must belong equally to both his groups α and β. I have found simple tunicates (*A. sordida*) on two small specimens of *H. coarctatus*. In one example they almost completely hid, and several were larger than, the crab. I do not know if anyone has observed *Hyas* "dressing" itself with tunicates. I should think it was an operation of some difficulty, at least in the case of *A. sordida*, which adheres pretty tightly to stones and shells. It cannot be said to be brilliantly coloured, so that its assumption by *Hyas* might be regarded as only an adaptation for concealment, as in the case of *Algæ*—belonging, therefore, to group α. It seems to me, however, very doubtful whether a small *Hyas* would, even if it could, willingly burden itself with such a serious incubus as half a dozen tunicates. Probably their presence is in no way due to any act of the crab's.

The shore-crab, as pointed out long ago by Prof. McIntosh, frequently suffers loss of sight by the usurpation of its orbit by a growing mussel, and the Norway lobster has been found with one eye grown over by a Polyzoan. Such foreign bodies are surely rather hurtful than protective, and the same may perhaps be said of the tunicates on *Hyas*. It is also a question whether the crab likes the smell of tunicates any better than its neighbours.

I think Mr. Garstang is wrong in assuming the inedibility of tunicates. Prof. McIntosh, in "The Marine Invertebrata and Fishes of St. Andrews," speaks of *Molgula arenosa* as being found abundantly, and of *Pelonaia corrugata* as occasionally in the stomach of the cod and haddock; and Mr. W. L. Calder-

wood has found *Pelonaia* in some numbers in the intestine of the common dab.

Amongst anemones, *A. mesembryanthemum* is certainly a favourite food of the cod, and is not uncommon on the carapace of *Cancer pagurus*. It is difficult to see in what way the anemone is there protective to the crab. Both young crabs and anemones (of this and some other species) are equally preyed on by the cod; and though the crab may perhaps be big enough (as in a recent specimen 5 inches broad) to enjoy immunity from the cod's attack, yet, by parading such a gaudy bait, it must at least run the risk of a severe shaking. It may be added that, in the last-named case, the anemone quitted the crab, when moribund, for a more desirable basis.

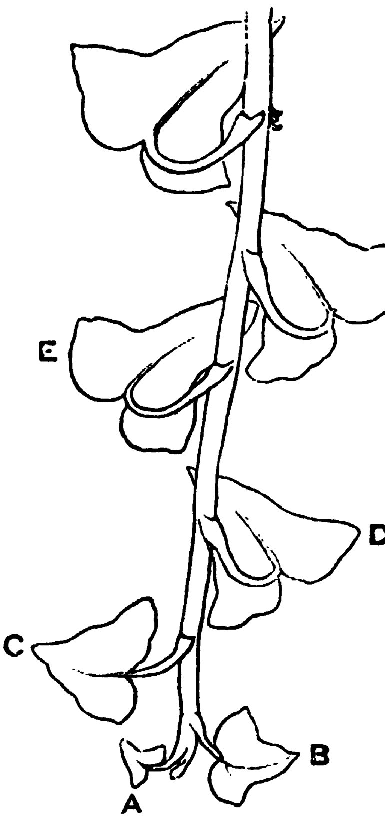
Abnormal Shoots of Ivy.

THE accompanying sketch represents a condition which is exhibited by a certain group of ivy plants in the neighbourhood of Plymouth. The plants are rooted upon the top of a high bank, which bounds the southern side of the road from Mount Edgcumbe to Tregantle; the branches pass downwards from the top of the bank on to its northern side.

The young shoots of each plant are conspicuous, because their leaves appear red, and so contrast strongly with the green of the older leaves. This appearance is due to the fact that the lower surface of each leaf is uppermost.

The sketch represents the terminal portion of a young shoot. The growing point is directed downwards. The three terminal leaves, A, B, C, have their upper surfaces directed upwards. The



leaves beyond these, however (D, E, &c.), are twisted in a twofold way. First, each leaf-stalk is twisted on its own axis, so that the lower side of the leaf is directed upwards; and secondly, the apex of each leaf is rotated through 180°, so that it points away from the growing point of the shoot which bears it, towards the root.

This twisted condition is exhibited by about twelve or fourteen leaves on every young shoot—say, through a dozen inches from the growing point. The older leaves lose both kinds of torsion, so that each old leaf has its upper side uppermost, and its apex is directed towards the growing point of the stem. The under sides of the older leaves have completely lost their red colour.

The condition described is exhibited by all the shoots of a plexus of ivy plants just beyond the fifth milestone from Mount Edgcumbe, on the road above mentioned. It is absent in all the many bushes and creeping masses of ivy which grow on the same bank of the road between this point and Mount Edgcumbe. Whether all the plants composing the abnormal plexus are the offspring of a single parent cannot now be determined.

Plymouth, March 10. W. F. R. WELDON.

Earth-Currents and the Occurrence of Gold.

GOLD has been so large a factor in the prosperity and greatness of Australia, that the interesting subject of the origin of gold drifts and reefs must always possess to us something more than a purely scientific attraction. In the earlier days of the goldfields there was among the diggers much speculation, of a scientific and semi-scientific nature, as to the processes by which Nature had produced the accumulations of coarse and fine gold dust which it was their business to extract from the alluvial drifts. The most obvious explanation, of course, was that the grains of gold had an origin similar to that of the *débris* and detritus of various characters which made up the alluvium itself; and this explanation seemed to harmonize so completely with the general processes of Nature that at one time it was almost universally accepted as the correct one. But many thoughtful mining authorities had their doubts upon the subject, and these doubts were not founded, as so frequently happens, upon mere prejudice, but were fortified by the fact that certain phenomena characteristic of the occurrence of drift gold were not only not explained by the "detrital hypothesis," as it is called, but were absolutely inconsistent with it. Chief among these objections may be mentioned the undoubted generalization that drift gold is nearly always purer than the gold in the reefs of the neighbourhood in which it occurs. No explanation as to the long distances to which grains of gold might be conveyed, or to the possible purifying effects of natural chemical action, made up any satisfactory explanation of the known facts, and accordingly under the detrital theory these facts had to remain shrouded in mystery. Then, again, it was a frequent occurrence for gold to be found so peculiarly embedded in pieces of wood, or in conjunction with natural crystals of minerals, such as the sulphides, that those who were constantly being brought into contact with such phenomena were firmly convinced that at all events there was a certain proportion of the gold found in alluvial drifts which had its origin in some other source than the breaking down of quartz reefs by the ordinary processes of Nature. The majority of those who held to this belief had at first but little scientific knowledge of natural reactions; and when questioned as to their theory on the subject, they were accustomed to say of the alluvial drift-gold, that it appeared to be actually growing—a statement which sometimes provoked, not unnaturally, a smile of pity for misplaced credulity.

These objectors, however, were right. Of this there is now scarcely the shadow of a doubt. It would be tedious to trace the steps by which such a strange conclusion has come to be virtually established. Suffice it to say that at the present day there are but few scientific men in Australia who have studied the subject who do not hold that by some agency or another the gold that is in our alluvial drifts has been formed, and probably is at present accumulating at the present moment, in its present position. It seems probable, indeed, that drift gold has its origin in the salts held in solution by the water by which it was formerly supposed to have been merely carried from one place to another. The most common salt of the precious metal is chloride of gold; and of this salt there is an appreciable quantity present in sea water along with the common sea salt, which, of course, is mainly chloride of sodium. In geological epochs, when the rocks of our present gold-fields were submerged below the ocean, and later on, when they held upon their surfaces vast imprisoned lakes of salt water, it is probable that they became saturated with sea water and retained large amounts of gold in solution. According to a computation quoted by Mr. Skey, the Government Geological Analyst for New Zealand, it is probable that every cubic mile of rock contains something like a million ounces of gold. Hence the underground streams of Australia, in certain districts, are particularly rich in salts of the precious metal, and there is an enormous area over which slight quantities of gold can always be obtained, while surface streams which are fed by deep-seated springs accumulate gold upon alluvial flats and hollows. Some of the gold found in such streams may undoubtedly be ascribed to the destruction of quartz reefs. It stands to reason that these reefs, like other rocks, must contribute to the *débris* in the beds of rivers and streams. But most of the purer alluvial coarse gold has evidently a different origin.

Up to this point, the new explanation of the origin of drift gold seems feasible, and, indeed, almost conclusive. The gold is present in minute quantities in the water of the drift, and this fact has been conclusively demonstrated experimentally by various investigators, among whom may be mentioned Messrs. Newberry and Skey. But it is one thing to prove that chloride of gold exists in the drift waters, and quite another thing to suggest in what manner and by what agency the precious metal has been reduced from its salt, and deposited in the form of coarse or fine grains or in that of large and strangely-shaped nuggets. Precipitation was the first and most obvious suggestion. The addition, for instance, of a minute quantity of sulphate of iron to a solution of chloride of gold would cause the formation of minute particles of metallic gold, and sulphate of iron, of course, is present in Nature abundantly. But such an explanation would only account for the formation of the very finest gold dust. It would give no solution of the origin of coarse gold and nuggets, nor would it account for any of the many peculiar anomalies of which I shall presently mention some striking examples.

In order to afford a possible extension of this purely chemical theory which might give a clue to the origin of nuggetty gold, it has been pointed out that if a crystal of some sulphide, such as iron pyrites, be immersed in a solution of chloride of gold, it will be covered with a film of metallic gold. Following the track of investigation thus apparently opened up, it has been ingeniously suggested that possibly the material of the metallic sulphide, and that of the golden film, may be regarded as a sort of miniature electric battery, in which the gold would form one anode and the pyrites the other. A current would pass between the two, and the result would be the deposition of metallic gold upon the film, at the same time that the material of the pyrites would continually become decomposed. The electroplater, in his laboratory, places the salt of gold in his bath, and uses an ordinary battery from which to obtain a current sufficiently strong to deposit gold upon the articles to be plated. But in this case it was suggested that the article to be plated, which was the film of gold itself, might be regarded as one of the elements supplying the current. The theory seems from the outset somewhat far-fetched, and it is open to very strong objections on the ground of improbability. The amount of material which the electroplater has to use up in order to deposit an ounce of gold is very considerable, even in the most efficient forms of batteries known to science. It is scarcely conceivable that a piece of pyrites, weighing about two pennyweights, would, by its decomposition, afford sufficient current to deposit an ounce of gold. Yet something of the sort would have to be established before it could be proved that electro-chemical action *in situ* supplies the electric current as a reducing agent.

In seeking for an explanation of the deposition of gold which would afford a surer or more probable basis for conjecture, I was at first mainly influenced by two remarkable facts which could hardly be referred to any imaginable phenomena of a chemical or electro-chemical origin. These were that in a drift supplying gold in abundance it is by no means uncommon to find a patch in which the gold gives out altogether, and is picked up further along the line; and the second was that there has always been observed at many of the leading goldfields a certain correspondence between the richness of the alluvial drifts and reefs and the points of the compass. The direction in which the richest drifts run may vary from one locality to another. But no matter how broken in contour the country may be, there is almost always a marked parallelism between the richest drifts.

Taking these and one or two other facts as a starting-point, I was led to form the hypothesis that the probable origin of the deposition of gold is to be found in thermo-electric earth-currents, probably generated by the unequal heating of the surface of the earth by the sun's rays in passing from east to west. This theory of earth-currents has attracted a good deal of attention in Australia, and it is remarkable how rapidly facts in support of it have been brought forward during the past few months. It would be impossible for me, within brief limits, to refer to all of these; but it will be of interest to summarize a few of the leading points:—

(1) The existence of earth-currents has been frequently demonstrated, and has attracted special attention since the invention of the telephone. In 1880, Prof. Trowbridge, of Harvard, conducted a series of experiments at the Observatory, and recorded it as one of his results that these currents appeared to be most pronounced along the water-courses.

(2) In Victoria remarkable instances of deflection of the compass have been particularly numerous, hinting at the presence of strong currents, more especially at the lines of junction between permeable and impermeable rocks.

(3) There is a remarkable relation between the conductivity of the adjacent rock country and the richness of an alluvial drift. Thus, in passing through slate or below an overhanging mass of basalt, the drift is generally richer than in passing through moist sandstone, suggesting that, where an earth-current is concentrated along the line of the water in consequence of the presence of rocks of low conductivity, the process of deposition has been facilitated.

(4) There are places at which the gold gives out altogether, although no discernible change has taken place in the nature of the country. These places seem to be the localities of a sort of short-circuiting, which we may readily suppose to take place very frequently in earth-currents.

(5) At particular pinched localities the current would be peculiarly strong, and would lead to the formation of nodules or nuggets of gold, the existence of which cannot be satisfactorily explained by any chemical theory hitherto advanced.

(6) Nuggets of an alloy of gold and copper have sometimes been met with, and the two metals have even been found to lie in alternate layers, suggesting that at one time a copper salt, and at another a gold salt, has been subjected to the action of a reducing current.

(7) In presence of a large amount of organic matter, it is almost invariably found that a drift becomes especially rich. The formation of acid by decomposition is what would be peculiarly required to facilitate the passage of an earth-current through the water of an underground drift, the existence of free acid being the requirement for an artificial electro-depositing bath.

(8) Conversely, the vicinity of large masses of calcite has been observed to be most inimical to the richness of a drift, and, of course, this could be explained by the fact that the carbonate of lime would destroy the free acid, and reduce the conductivity of the water so as to impede the transmission of a current.

(9) The peculiar shapes of the grains of what is known as coarse gold, are very suggestive of the action of a feeble current in piling up the metal upon the prominent portions, and leaving deep indentations between. Electric action of an extraneous nature is also strongly indicated by the strange strings and filaments which are constantly being met with.

(10) If we accept the crenitic theory of the origin of quartz reefs, the theory of earth-currents would at once apply with particular force to show how the action of such currents in hot siliceous solutions would produce a formation of gold simultaneous with that of quartz, thus accounting for the finely divided state of the gold in such reefs.

(11) At the same time it is necessary to account for the existence of the large masses of gold which are sometimes found associated with quartz, at places where the reefs become narrow in pinched localities. The theory of precipitation cannot account for these. But that of earth-currents would naturally lead us to expect the phenomenon, because in such a locality, while the formation of quartz would be retarded, the formation of gold would be accelerated by the concentration of the current as already explained.

The hypothesis is thus well supported by *primâ facie* evidence. For the experimental detection of earth-currents on goldfields I have strongly recommended the close observation of the most minute deflections of the magnetic needle, especially in underground workings. I believe also that the use of the telephone, as in Prof. Trowbridge's experiments, will be of great service in indicating the lines of greatest conductivity in the earth's crust, and in enabling us to decide whether these are identical in goldfields with those lines in which the drifts contain the richest gold.

GEORGE SUTHERLAND.
Angas Street, Adelaide, South Australia.

THE PRIMITIVE TYPES OF MAMMALIAN MOLARS.

So much light has recently been thrown on the origin and mutual relations of the Mammalia by the labours of the Transatlantic palæontologists, that in the case of the limbs we have long since been able to trace the evolution of the specialized foot of the Horse from

that of the five-toed *Phenacodus* (see NATURE, vol. xl. p. 57). Till quite lately, however, we have been unable to follow the mode of evolution of the more complicated forms of molar teeth from a common generalized type although Prof. Cope, by his description of the so-called "tritubercular" type of molar structure, paved the way for the true history of this line of research.

The common occurrence of this tritubercular type of dentition among the mammals of the Lower Eocene at once suggests that we have to do with a very generalized form of tooth-structure; and by a long series of observations Prof. H. F. Osborn, of Princeton, New Jersey, has succeeded, to a great extent, in showing how the more complicated modifications of molars may have been evolved from this generalized type. These observations are of so much importance towards a right understanding of the phylogenetic relationships of the Mammalia that a short summary cannot fail to be interesting to all students of this branch of zoology.

The tritubercular molar (Fig. A, 6), consists of three cusps, cones, or tubercles, arranged in a triangle, and so disposed that those of the upper jaw alternate with those of the lower. Thus, in the upper teeth (Fig. A, 7), there are two cusps on the outer side, and one cusp on the inner side of the crown; while in the lower teeth (Fig. A, 8, 8*a*) we have one outer and two inner cusps. This type, when attained, appears to have formed a starting-point from which the greater number of the more specialized types have been evolved. The Monotremes, the Edentates, perhaps the Cetaceans, and the extinct group of Multituberculata (*Plagiaulax* and its allies), must, however, be excepted from the groups whose teeth have a tritubercular origin.

It appears probable, indeed, that "trituberculism," as this type of tooth-structure may be conveniently termed, was developed from a simple cone-like tooth during the Mesozoic period, and that in the Jurassic period it had developed into what is termed the primitive sectorial

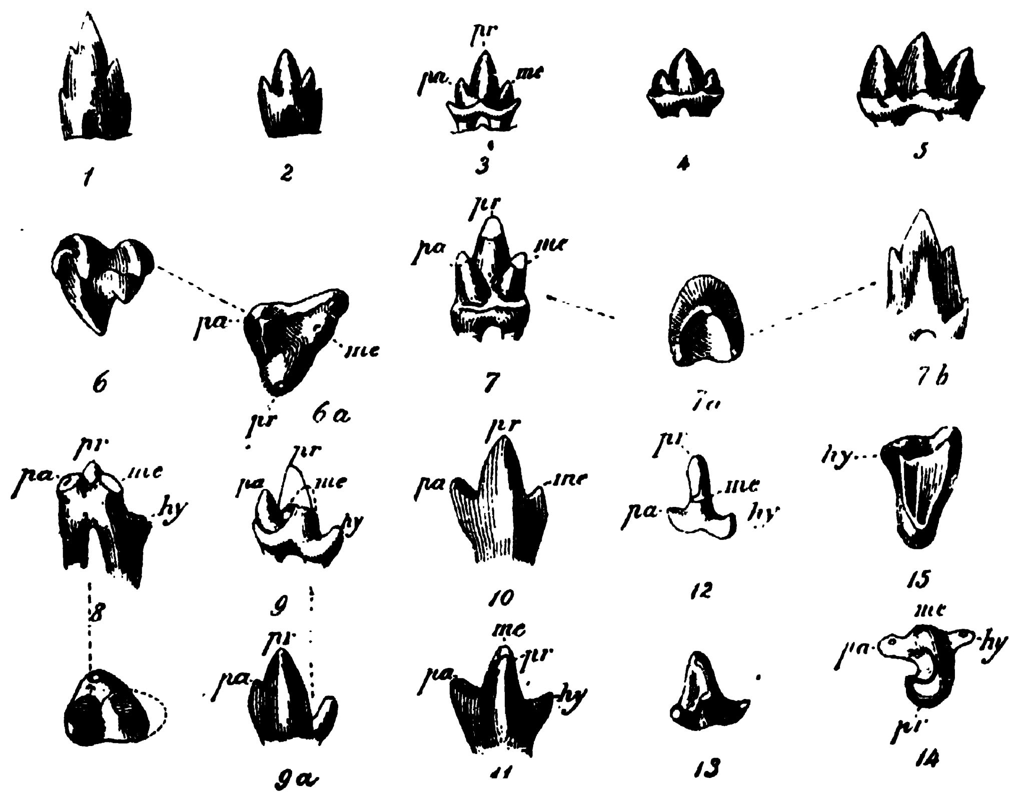


FIG. A.—Types of Molar Teeth of Mesozoic Mammals. 1–5, Triconodont Type (1, *Dromatherium*; 2, *Microconodon*; 3, *Amphilestes*; 4, *Phascolotherium*; 5, *Triconodon*). 6, 7, 10, Tritubercular Type (6, *Peralestes*; 7, *Spalacotherium*; 10, *Asthenodon*). 8–9, 11–15, Tuberculo-Sectorial Type (8, *Amphitherium*; 9, *Peramus*; 11, *Dryolestes*; 12, 13, *Amblotherium*; 14, *Achyrodon*; 15, *Kurtodon*). 6 and 15 are upper, and the remainder lower molars. *pa*, paraconid; *pr*, protoconid; *me*, metaconid; *hy*, hypoconid. In the upper teeth the termination ends in cone.

type (Fig. A, 9). The stages of the development of "trituberculism" may, according to Prof. Osborn, be characterized as follows:—

(1) The *Haplodont* type.—This is a hypothetical type at present undiscovered, in which the crown of the tooth forms a simple cone, while the root is probably in most cases single, and not differentiated from the crown.

(*a*) The *Protodont* sub-type.—This sub-type is a slight advance on the preceding, and is represented by the American Triassic genus *Dromatherium*. The crown of the tooth (Fig. A, 1) has one main cone, with fore-and-aft accessory cusps, and the root is grooved.

(2) The *Triconodont* type.—In this Jurassic type the crown (Fig. A, 4, 5) is elongated, with one central cone, and a smaller anterior and posterior cone situated in the same line; the root being differentiated into double fangs. *Triconodon*, of the English Purbeck, is the typical example.

(3) The *Tritubercular* type.—In this modification the crown is triangular (Fig. A, 7), and carries three main cusps or cones, of which the central one is placed internally in the upper teeth (Fig. A, 6), and externally in the lower molars (Fig. A, 7). The teeth of the Jurassic *Spalacotherium* are typical examples. In the first and second types the molars are alike in both the upper and lower jaws; but in the third or tritubercular type, the pattern is the same in the teeth of both jaws, but with the arrangement of the homologous cusps reversed. These features are exhibited in Fig. B.

These three types are regarded as primitive, but in the following sub-types we have additional cusps grafted on to the primitive tritubercular triangle, as it is convenient to term the three original cusps.

(*a*) *Tuberculo-sectorial* sub-type.—This modification of the tritubercular type is found in the lower molars, like those of *Didelphys*. Typically the primitive tritubercular triangle is elevated, and the three cusps are connected by cross ridges, while a low posterior talon or heel is added (Fig. A, 9). This modification embraces a quinquetubercular form, in which the talon carries an inner and

an outer cusp; while by the suppression of one of the primitive cusps we arrive at the quadritubercular tooth, bunodont tooth (Fig. C), like that of the Pigs. In the upper molars the primitive triangle in what is termed the secodont series may remain purely tricuspid. But by the development of intermediate tubercles in both the secodont and bunodont series a quinquetubercular form is reached; while the addition of a postero-internal cusp in the bunodont series gives us the sextubercular molar.

There is no doubt as to the homology of the three primary cusps in the upper and lower molars; and Prof. Osborn proposes the following series of terms for all the cusps above mentioned. The first secondary cusps (hypocone and hypoconid) respectively added to the upper and lower molars are also evidently homologous, and modify the crown from a triangular to a quadrangular form; but there is no homology between the additional secondary cusps of the upper molars termed protoconule and metaconule with the one termed ectoconid in the lower molars.

Terms applied to the cusps of molars:—

Upper Molars.			
Antero-internal cusp .	=	Protocone	—pr.
Postero- ,, ,, or 6th cusp	=	Hypocone	—hy.
Antero-external ,, .	=	Paracone	—pa.
Postero- ,, ,, .	=	Metacone	—me.
Anterior intermediate cusp .	=	Protoconule[1]	—ml.
Posterior ,, ,, .	=	Metaconule	—pl.
Lower Molars.			
Antero-external cusp .	=	Protoconid	—pr^d.
Postero- ,, ,, .	=	Hypoconid	—hy^d.
Antero-internal or 5th cusp .	=	Paraconid	—pa^d.
Intermediate, or antero-internal cusp (in quadritubercular molars)	=	Metaconid	—me^d.
Postero-internal cusp .	=	Entoconid	—en^d.

Having thus worked out the homology and relations of the tooth-cusps, Prof. Osborn gives some interesting observations on the principles governing the development

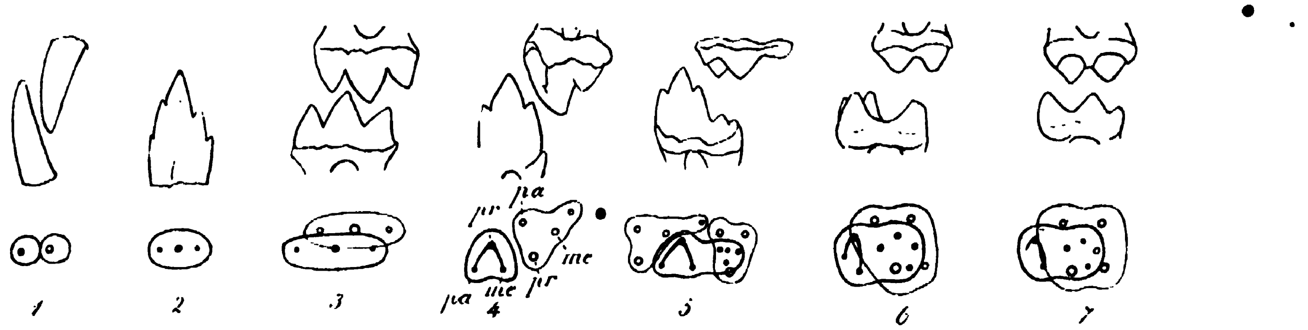

FIG. B.—Upper and Lower Molars in mutual apposition. 1, *Delphinus*; 2, *Dromatherium*; 3, *Triconodon*; 4, *Peralestes* and *Spalacotherium*; 5, *Didymictis*; 6, *Mioclænus*; 7, *Hyopsodus*. Letters as in preceding figure.

of these cusps. It is considered that in the earliest Mammalian, or sub-mammalian, type of dentition (Haplodont), the simple cones of the upper and lower jaws

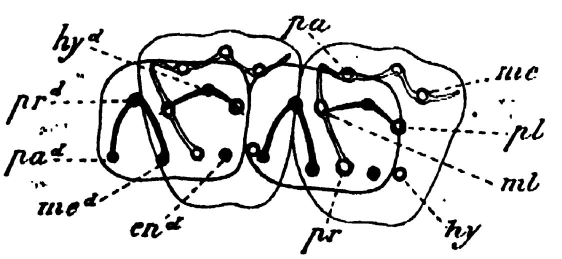

FIG. C.—Diagram of two upper and lower quadritubercular molars in apposition. The cusps and ridges of the upper molars are in double lines, and those of the lower ones in black. The letters refer to the table given above. The lower molars are looked at from below, as if transparent.

interlocked with one another, as in the modern Dolphins (Fig. B, 1). The first additions to the primitive protoconid appeared upon its anterior and posterior borders, and the growth of the para- and metaconids involved the necessity of the upper teeth biting on the outer side of the lower (Fig. B, 2), this condition being termed anisognathism, in contrast to the isognathism of the simple interlocking cones. In the typical tritubercular type (Fig. A, 7) it has been suggested that the para- and metaconids were rotated inwards from the anterior and posterior borders of the triconodont type; but it is quite possible that they may have been originally developed in their present position. By the alternation of the primitive triangle in the upper and lower jaws of the tritubercular type, the retention of an isognathous arrangement is permitted, the upper and lower teeth biting directly against one another.

Finally, Fig. C shows the mutual relations of the upper and lower teeth of the complicated quadritubercular molars, with the positions held by the primitive tritubercular triangles.

OXFORD "PASS" GEOMETRY.

ἀγεωμέτρητος μηδεὶς ἐνταυθοῖ εἰσίτω.

WHETHER poultry are to be regarded as descended from a primeval egg or a primeval hen, is a question on which some amount of scholastic ingenuity is supposed to have been exercised, and whether teachers or examiners are responsible for defective training in geometry is a question on which much might, more or less unprofitably, be said, and on which teachers and examiners may be expected to take different views. Happily for the mental equipment of the present generation of students, many teachers and examiners, avoiding barren controversy, have both laboured, as far as in them lies, to encourage soundness and thoroughness.

Probably, the old-world teachers who, hearing a "Euclid" lesson with the open Simson in their hand, looked upon "therefore" as an unwarrantable substitute for "wherefore," and could not be induced to accept "angle CAB" as a legitimate equivalent for what they saw in the text presented as "angle BAC," are fast disappearing, if not already extinct. Unfortunately, we are still under the influence of bad examination papers. Take, for instance, the papers set last year at Responsions. The sole directions from the examiner to the printer, necessary for getting these set up, might have been, and very likely were, as follows:—

Trinity.		Hilary.		Michaelmas.	
(1) I. 4	(6) I. 46	(1) I. 5	(6) I. 48	(1) I. 2	(6) I. 45
(2) I. 14	(7) II. 5	(2) I. 10	(7) II. 3	(2) I. 7	(7) II. 6
(3) I. 21	(8) II. 7	(3) I. 17	(8) II. 6	(3) I. 26	(8) II. 10
(4) I. 22	(9) II. 12	(4) I. 31	(9) II. 9	(4) I. 34	(9) II. 12
(5) I. 42	(10) II. 14	(5) I. 39	(10) II. 14	(5) I. 46	(10) II. 14

[1] The symbols *ml.* and *pl.* should properly apply respectively to the metaconule and protoconule, but since they bear the opposite signification in Fig. C, they are placed as above.

We believe that those qualified to give an opinion will agree as to the tendency of papers like these. They are direct incentives to learning propositions by rote—a practice to which beginners are by nature only too prone, without being encouraged by the grave authority of an ancient University: and they tend to paralyse any efforts a tutor may make to teach his subject intelligently. How is he to get pupils to listen to any discussion of difficulties, or to care for any deductions from the propositions, when they know as well as he does that not a mark can be gained by anything which goes beyond a bare knowledge of the Simsonian text?

Well might the Council of the Association for the Improvement of Geometrical Teaching, in its last Report, "regret to notice that the Euclid papers set for Responsions at Oxford still consist exclusively of bookwork," and remark that "the entire absence of riders or other questions designed to test the real knowledge of the student seems calculated to foster 'cram.'" The Council confined itself, as we have done, to the "Responsions" papers, but its remarks apply with equal force to "Moderations." The Euclid paper in the "First Public" and "Second Public" of Michaelmas 1889 are, in effect:—

"Write out IV. 1, III. 10, 3rd case of III. 35, III. 2, III. 25, III. 28, III. 12, III. 17, IV. 4, IV. 7.

"Define plane superficies, rhomboid, sector, similar segments, ratio, ex æquali.

"Write out the three postulates and the twelfth axiom.

"Write out I. 7, I. 29, I. 48, II. 12, III. 15, III. 26, IV. 6, VI. 5, VI. 18."

Though we regret the absence of "riders," we do not attach so much importance to it as to that of "other" questions arising naturally from the definitions, axioms, postulates, and propositions set to be written out: questions, for instance, on the redundancy of the definitions; on the distinction between the general and the geometrical axioms; on the axioms tacitly assumed by Euclid; on the truth or falsehood of the converse of a given proposition; on the interdependence of two contrapositives; or on the difficulties of Euclid's treatment of parallels.

It is instructive to contrast the Mathematical Responsions papers with those set in the classical part of the same examination. In these the University is by no means satisfied, as in the mathematical, with a knowledge which may be obtained by efforts of the memory alone, but applies the sharp test of prose composition and "unseens." To this inequality we draw the special attention of readers of NATURE. Compare the course open to a classical man with that which lies before one who intends to take his degree in science or mathematics. The classical man appears to have everything in his favour: he most likely knows enough mathematics to feel quite comfortable as to the paltry modicum required at Responsions. The other is in a very different position. If he has attained to anything like scholarship in his own subject, it will only be in rare cases that he can hope to get through Responsions without devoting a large amount of valuable time towards the acquirement of some facility in prose composition. We should like to see a vigorous protest by the science graduates against this anomaly.

PRZEWALSKY'S ZOOLOGICAL DISCOVERIES.[1]

WITH great satisfaction naturalists will observe that a complete account of Przewalsky's zoological observations and discoveries is to be given to the world, and has in fact been for some time in course of publication. The great Russian explorer, although perhaps best known in Western Europe as a geographical traveller, was at heart a naturalist, and one of no mean rank. Those who have read the narratives of his four great journeys will recollect how full they are of notes on the animals and plants met with during his routes. The specimens obtained by him and his companions were carefully preserved, and deposited in the Museum of the Imperial Academy of Sciences at St. Petersburg. Up to the present time these collections have only been made known to the public by various fragmentary accounts of them in scientific journals, and in the appendices to Przewalsky's volumes of travels, which were in many cases of the most unsatisfactory character. The Imperial Crown Prince Nicolas of Russia has now, however, placed at the disposal of the Imperial Academy, in whose Museum Przewalsky's collections are stored, a sum sufficient to cover the cost of the publication of a connected account of them. To no more worthy object could Royalty devote its income, and the resulting volumes promise to be alike a credit to the great nation to which Przewalsky belonged, and to form a very material contribution to zoological science.

As is almost the universal and necessary custom nowadays, the different branches of the collections to be investigated have been placed in the hands of different specialists. The mammals had been undertaken by Eugene Büchner, the Conservator of the Division of Mammals in the Academy's Zoological Museum. Herr Theodor Pleske, who has lately succeeded Herr Russow in the charge of the birds of the same Museum, supplies the portion of the work relating to the objects under his care. Similarly, to Herr S. Herzenstein have been assigned the fishes. Each section is prepared on a similar plan. The text is given in parallel columns of Russian and German. We cannot complain of a great national work like the present being published primarily in the national language, but our thanks should be given to the learned Academy for letting us have it also in a tongue generally understood by scientific men. The work is well illustrated, and the plates are excellently drawn, those of the mammals and birds mostly by Mützel, the well-known German lithographic artist. Up to the present time we have seen three parts of the mammals, one of the birds, and two of the fishes of this important work, which is a credit alike to the Academy which has produced it, and to the distinguished personage who has supplied the necessary means.

[1] "Wissenschaftliche Resultate der von N. M. Przewalski nach Central-Asien unternommenen Reisen: auf Kosten einer von seiner Kaiserlichen Hoheit dem Grossfürsten Thronfolger Nikolai Alexandrowitsch gespendeten Summe." Herausgegeben von der Kaiserlichen Akademie der Wissenschaften. Zoologischer Theil. (St. Petersburg, 1888–89.)

NOTES.

THE Chemical Society will this year for the first time hold its anniversary meeting (March 27) in the afternoon at 4 p.m., and the Fellows and their friends will dine together in the evening at the Whitehall Rooms, Hotel Métropole. It is hoped that the Fellows will signify their approval of this alteration by attending in considerable numbers.

A MEETING was held in Berlin on Monday, March 10, under the auspices of the German Chemical Society, to celebrate the 25th anniversary of the promulgation of Prof. Kekulé's theory of the constitution of the aromatic compounds. A very large number of chemists assembled in the Rathhaus in the afternoon. After an introductory address by the President, Prof. v. Hofmann, Prof. A. Bayer delivered a lecture in which he pointed out how completely modern investigations had confirmed Kekulé's views. A congratulatory address from the German Chemical Society was then presented to Prof. Kekulé. Prof. Armstrong attended on behalf of the London Chemical Society, Prof. Korner on behalf of the Italian chemists, Prof. Bischof on behalf of the Russian chemists; and besides the addresses presented by those representatives, there were very numerous letters

and telegrams of congratulation from various sources. Dr. Glover, on behalf of German artificial dye-stuff manufacturers, then presented a most admirable portrait of Prof. Kekulé which had been painted by the celebrated painter Angeli; this is to be placed in the Berlin galleries. Prof. Kekulé returned thanks in an eloquent address. Subsequently a banquet was held which was very numerously attended.

LORD RAYLEIGH has been elected a correspondent of the Paris Academy of Sciences in the department of physics.

THE discourse to be given by Lord Rayleigh at the Royal Institution on Friday evening, March 28, will be on "Foam."

MR. H. CARRINGTON BOLTON, the eminent American bibliographer, wishes to associate himself with those who recommend the system of Russian transliteration, explained lately in NATURE (p. 397). His letter was not received in time to permit of his name being included in the list of signatures.

THE visit of the Iron and Steel Institute to America is likely to be remarkably successful. At a meeting held the other day at New York, upon the invitation of Mr. Andrew Carnegie, a committee was appointed to arrange a reception for the members. The Philadelphia Correspondent of the *Times* says so many invitations have been received from various parts of the country that the belief is that the month given to the visit will be insufficient. The members will meet in New York. There will also be an international session at Pittsburg.

A STATED meeting of the Royal Irish Academy was held in Dublin on the 15th inst., at which the President and Council for the ensuing year were elected. Prof. Sollas, F.R.S., read a paper on the mica which occurs in well-formed crystals in the famous geodes of the Mourne Mountain granite: it was described as a lithium mica of the species Zinnwaldite. Most of the crystals possessed an exquisitely defined zonal structure, and in a single crystal a change in colour, density, composition, and in the magnitude of the angle of the optic axes could be traced on passing from the centre to the surface; this gradual transition from a more ferro-magnesian character near the centre to a more alumino-alkaline one near the surface was compared to the change from a more anorthite-like to a more albitic character, which accompanies the growth of many zonal felspars. This subject is also referred to in Prof. Sollas's paper on the granites of Leinster, which is to appear in the Academy's Transactions. The Report of the Council, giving the details of work done by the Academy during the past year, with notices of deceased members—among these John Ball, F.R.S., Sir Robert Kane, F.R.S., and Robert McDonnell, F.R.S.,—was read and adopted. Dr. E. Perceval Wright, Secretary to the Academy, was elected, in the place of the late Sir R. Kane, a visitor to the Museum of Science and Art, Dublin.

THE Royal Society of Medical and Natural Sciences of Brussels offers a gold medal of the value of 200 francs for the best essay on the influence of temperature on the progress, duration, and frequency of karyokinesis in an example belonging to the vegetable kingdom. The essay must be written in French, and must be sent in before July 1 to Dr. Stiénon, 5 Rue du Luxembourg, Brussels.

MR. J. WERTHEIMER, head master of the Leeds School of Science and Technology, has been elected to the head mastership of the Merchant Venturers' School, Bristol, the largest technical school in the West of England.

RECOGNIZING the difficulty experienced by Western naturalists in following the valuable scientific work now carried on in Russia, a number of influential men of science of that country have arranged for the publication of a monthly review—the *Vyestnīk Estestvoznaniya.* This will consist of original articles and short reports, with French *résumés*, and an index, in French, to Russian periodical scientific literature; the subjects included will be zoology, botany, physiology, geology, and microscopical technology, with the allied sciences. As, with the exception of Nīkītīn's admirable geological bibliography, no adequate attempt has been made to record Russian general scientific literature, this review will supply a very general want. The facts that it is published under the auspices of the St. Petersburg Society of Naturalists, and that the list of promised contributors includes most of the leading Russian naturalists, are sufficient guarantee for its value. The bibliographical index commences in the second number. The first consists of eight original articles. W. Wagner treats of the Infusoria of the body-cavity of Sipunculus and Phascolosoma; J. Wagner of some points in the development of Schizopods; Schīmkevīch of the alternation of generation in the Hydromedusæ; Borodīn and Tanfīl'ev contribute botanical articles, the former discussing the nature and distribution of dulcite, and the latter the causes of the extinction of *Trapa natans.* Geology is represented by an account of the Devonian rocks of Mughodzhares, a criticism of Lévy's classification of the eruptive rocks by Polyenov, and an interesting account of the formulæ and relations of the different chemical types of the eruptive rocks by F. Levinson-Lessīng. The subscription to the review, it may be added, is 3 roubles 50 kopecks, and the office of publication, the Society of Naturalists, St. Petersburg University.

THE Vienna correspondent of the *Standard* telegraphed as follows on Monday:—"Dr. Eder, Professor of the Photographic Institute of Vienna, has announced that a photographer named Verescz, living in Klausenburg, Transylvania, has succeeded in solving the problem of photographing in natural colours. Up to the present, only the shades between deep red and orange can be retained, and even these, if exposed to the light, fade in from two to three days; but the experiments are being continued, with good prospects of complete success."

RECENTLY Lord Reay, the Governor of Bombay, laid the foundation-stone at Poona of a Bacteriological Laboratory, which is to be annexed to the College of Science in that town. Dr. Cooke, the Principal of the College, to whose efforts the establishment of the Laboratory is due, stated that it was originally intended that the study of the diseases of the lower animals in Poona should be directed to check the losses from anthrax in cattle by the introduction into India of protective inoculation. With this object two Bengal students at the Cirencester Agricultural College underwent a course of study at M. Pasteur's laboratory in Paris. One of these gentlemen devoted his attention entirely to sericulture, the other studied M. Pasteur's system of vaccination against anthrax. He returned to India, and has since conducted some experiments on cattle in Calcutta. Subsequently, Mr. Cooper, of the Veterinary Service, was deputed to M. Pasteur's Institute for instruction in the system of inoculation against anthrax. While in Paris, Mr. Cooper submitted a report, and explained that for the work in question a special laboratory would be required. At the same time he advocated the adoption of artificial gas for the culture-stoves and glass-blowing, and for the purpose of obtaining the high temperature required for sterilizing vessels, instruments, &c. Subsequent inquiry showed that anthrax is not the only contagious disease of a fatal nature with which the Indian cattle-owner has to contend. He has also to take into account rinderpest, tuberculosis, pleuro-pneumonia, and, in a minor degree, foot and mouth disease. It was, therefore, evident that if an institution was established for the preparation of an anthrax vaccine its value would be greatly enhanced if diseases other than anthrax could receive attention. The main objects of the Poona

Laboratory therefore are:—(*a*) The preparation of anthrax vaccine for despatch to districts where anthrax prevails. (*b*) The conduct of experiments in rinderpest with a view to the discovery of the pathogenic micro-organism of the malady, its cultivation in broth and other media, and attenuation, so as to provide a vaccine that shall give immunity to animals in rinderpest-infected districts. (*c*) Experimental research into the epizootic diseases generally of the ox and horse. (*d*) The instruction of trained native veterinarians in a proper method of performing vaccination and of the precautions necessary to avoid risk of septic infection.

ON March 17, at six minutes past 11, a severe shock of earthquake was felt at Bonn, and reports from the surrounding districts on the following morning showed that it was very generally perceived in the vicinity of the town. On March 18, in the morning, a strong shock of earthquake was felt at Malaga and the neighbouring towns. The inhabitants were greatly alarmed, but no damage is reported.

ACCORDING to a telegram sent from New York by Reuter's Agency on March 15, the captain of the steamer *Slavonia* reported having encountered a waterspout during the voyage from Europe. The vessel sustained no damage.

THE Pilot Chart of the North Atlantic Ocean for the month of March states that the weather during February was much more moderate than during the two preceding months. An area of very high barometer extended over nearly the entire length of the Transatlantic steamship routes during the first five days. After this date the pressure fell, and gales of varying force were experienced from time to time. The most important of these storms was one south of Newfoundland on the 21st, whence it moved rapidly eastward. The storm on the 11th in about lat. 49° 30′ N., long. 22° W., was also of considerable energy. The most extensive fog bank reported during the month occurred on the coast from the 24th to the 26th, from Boston to Norfolk. The unprecedentedly large amount of ice this season has been the cause of considerable delay and damage to vessels; there are not only vast fields of ice, but also a very large number of bergs, some of which are of enormous dimensions. The importance of the knowledge of ice movements to navigation is recognized to be so great, that the Navy Department has, at the request of the U.S. Hydrographer, despatched an officer to Halifax and St. John's to collect information upon the ice movements during this season and past years, for the purpose of facilitating predictions of the general movements in future. A petition is also being drawn up for transmission to the Canadian Government to take such steps as they may deem advisable to obtain as thorough a knowledge as possible of the currents in the Gulf of St. Lawrence and adjacent waters, on account of their dangerous character during thick weather.

IN the summary of a meteorological journal kept by Mr. C. L. Prince, at his observatory, Crowborough, Sussex, during 1889, he draws attention to the great preponderance of north-east wind over all other wind currents, and more particularly over that from the south-west, which has obtained during the last five years. He has examined his registers for the thirty-one years ending with 1889, and finds that between 1859 and 1883 there were only two years, viz. 1864 and 1870, in which the north-east wind has been in excess. In 1884 the north-east and south-west winds were nearly balanced, but during the last five years the average frequency has been north-east 102, south-west 72. Comparative observations would be interesting with the view of seeing whether this reversal of the ordinary conditions holds good for other stations. The Greenwich observations show that this great preponderance of north-east wind is not borne out there, at all events in all of the years mentioned.

TECHNICAL instruction, according to the *Times of India*, now takes a leading place in the educational programme of the Central Provinces. A year ago an entirely new curriculum was devised, whereby, among other changes, agricultural and engineering classes were established at Nagpore; the scholarship rules were revised with special reference to technical education; drawing-masters were appointed at a large number of schools, and every encouragement was given to the study of that subject; and new subjects of a technical and scientific character were grafted on to old school programmes. When the fact is taken into consideration that the year was one of transition, the progress made may be pronounced most satisfactory. Eleven students out of thirty who applied were admitted into the engineering class after a test as to general education. These did well, and most of them have entered on a second year's course. The agricultural class had an average strength of twenty-five throughout the year, the pupils working on the model farm and in the laboratory established in connection with this technical education scheme. No fewer than seventeen of the lads came through the ordeal of a strict examination at the end of the session. When it is remembered how largely the economic future of India will depend on the development of her agricultural resources, the value of this work, now fairly initiated in the Central Provinces, cannot be over-estimated.

IN the current number of the *American Naturalist* Mr. R. E. C. Stearns continues his interesting series of papers on the effects of musical sounds on animals. One of his correspondents writes:—"Some time since I had an ordinary tortoise-shell cat, which had a peculiar fondness for the tune known as 'Rode's Air.' One day I chanced to whistle it, when, without any previous training, she jumped on my shoulder, and showed unmistakable signs of pleasure by rubbing her head against mine, and trying to get as near my mouth as possible. I have tried many other tunes, but with no avail." Captain Noble, of Forest Lodge, Maresfield, England, testifies that he formerly had a cat which displayed a corresponding sensitiveness, but it was only by plaintive tunes that she was affected. When such an air was whistled, she would climb up, and try to get her mouth as close as possible to that of the whistler. "I used as a rule," says Captain Noble, "to whistle the 'Last Rose of Summer,' when I wished her to perform. I never could satisfy myself as to her motive in putting her mouth to mine. The most feasible conjecture that I was able to make seemed to be that she imagined me to be in pain, and in some way tried either to soothe me, or to stop my whistling."

A PAPER on forestry in India and the colonies was read last week by Dr. W. Schlich before the Royal Colonial Institute. He said that for 700 years a gradual destruction of the forests of India had gone on. Under British rule the process had been hastened by the extension of cultivated and pasture land, and by the laying down of railways. After a time difficulty was experienced in meeting demands for timber, and in the early part of the century a timber agency was established on the west coast, while, in 1873, a teak plantation on a large scale was made at Nilambur. Through the energy of a few officials the matter was kept before the public, and in 1882 the Forests Department of Madras was entirely reorganized. Several Acts were passed to provide for the management of the forests under the protection of the State, and a competent staff of officers was provided, to be reinforced from time to time by those educated at Cooper's Hill College. Under the charge of the Department were some 55,000,000 acres of forest lands, and the figures relating to the cost of the work done were very satisfactory. Dr. Schlich then gave an account of the action of the Australian colonies with regard to the regulation of wooded lands by the State, contending that in no case had sufficient steps been taken to ensure a lasting and continuous supply of timber.

We print to-day a review of Dr. Sydney J. Hickson's valuable work, "A Naturalist in North Celebes." It may be well at the same time to call attention to an "Album" which has been sent to us, containing reproductions of photographs taken in Celebes. The collection has been formed by Dr. A. B. Meyer, director of the Zoological and Ethnographical Museum of Dresden, and includes 37 plates, on which about 250 reproductions are printed. In 1870 and 1871 Dr. Meyer spent some time in Celebes, and the greater number of the photographs which have been reproduced he brought back with him. Others he has received from friends. We cannot say that the process employed has always yielded perfectly satisfactory results; nevertheless, the "Album" contains many representations that cannot fail to interest students of anthropology and ethnography. There are groups of portraits from northern, central, and southern Celebes, and any one who carefully studies them will find that they give him a very vivid idea of the various types of the native population. The tables are accompanied by short explanatory notices, some of the best of which are by Dr. J. G. F. Riedel, Utrecht. The work is edited by Dr. Meyer, and issued by Messrs. Stengel and Markert, Dresden.

Messrs. Macmillan and Co. have published a second edition of Sir John Lubbock's well-known "Scientific Lectures." The author includes in this edition the Presidential address read by him before the Institute of Bankers in 1879. The address contains many interesting suggestions as to the development of coinage, and is illustrated by two excellent plates representing ancient coins.

We have received the fifth volume of "Blackie's Modern Cyclopædia," edited by Dr. Charles Annandale. The volume includes words from "Image" to "Momus," and the articles, so far as we have tested them, are, like those of the preceding volumes, concise and accurate.

The Literary and Philosophical Society of Liverpool has published Nos. 41, 42, and 43 of its Proceedings. Among the papers printed, we may note "Life and Writings of the Hon. Robert Boyle," by Mr. E. C. Davies; "An Ideal Natural History Museum," by Prof. Herdman; "On the Remains of Temperate and Sub-Tropical Plants found in Arctic Rocks," by the Rev. H. H. Higgins: "Notes on the Cooke Collection of British Lepidoptera," by Mr. J. W. Ellis; "Lake Lahontan, an Extinct Quaternary Lake of North-West Nevada, U.S.A.," by Mr. R. McLintock; "On the Individuality of Atoms and Molecules," by the Rev. H. H. Higgins; note on the foregoing, by Prof. Oliver J. Lodge; "The Complete Analysis of Four Autopolar 10-Edra," by the Rev. T. P. Kirkman; and "On the Cradle of the Aryans," by Principal Rendall.

Mr. Fletcher, the well-known manufacturer of gas appliances, has just issued a little work of 70 pages on "Coal Gas as a Fuel" (Warrington: Mackie and Co.). Perhaps no one has given more attention to the subject than Mr. Fletcher, and his book is therefore of considerable importance. He gives an account of the precautions necessary to obtain the greatest efficiency in every case where coal gas can be applied—in the kitchen, bath-room, greenhouse, workshop, and laboratory. There is a useful chapter giving instructions to fitters with respect to flues and dimensions of service pipes. All who consume gas for purposes other than ordinary house illumination, will do well to read Mr. Fletcher's book.

A curious observation relating to influenza is quoted in *La Nature* from a Copenhagen journal. At the Royal Institution for education of deaf-mutes there, the pupils (about 70 boys and girls) have for seven years been regularly weighed every day in groups of 15 and under. This new experiment has yielded some interesting results. Thus it has been found that the children's growth in weight has occurred chiefly in autumn and in the first part of December; there is hardly any in the rest of winter and in March and April, and a diminution then occurs till the end of summer. Last year proved an exception. The curves of weight were quite like those of previous years till November 23. In the four weeks thereafter, while each child has usually gained on an average over 500 grammes, the girls last year gained nothing, and the boys only 200 grammes each (less than two-fifths of the normal amount). The contrast with 1888 was even more remarkable, 700 grammes having been the average four-weeks' gain in that year. There was no modification as regards food or other material conditions. Now, the influenza epidemic appeared in Copenhagen towards the end of November. While six of the professors at this institution were attacked, there were no pronounced cases among the pupils; but it is supposed that germs of the disease having entered the place, the struggle with these on the part of the children absorbed so much vital force that the organs of nutrition failed to give the normal increase of weight after November 23.

A remarkable fall of a miner down 100 metres of shaft (say 333 feet) without being killed, is recorded by M. Reumeaux in the *Bulletin de l'Industrie Minérale.* Working with his brother in a gallery which issued on the shaft, he forgot the direction in which he was pushing a truck, so it went over and he after it, falling into some mud with about 3 inches of water. He seems neither to have struck any of the wood *débris*, nor the sides of the shaft, and he showed no contusions when he was helped out by his brother after about ten minutes. He could not, however, recall any of his impressions during the fall. The velocity on reaching the bottom would be about 140 feet, and time of fall 4·12 seconds; but it is thought he must have taken longer. It appears strange that he should have escaped simple suffocation and loss of consciousness during a time sufficient for the water to have drowned him.

An extremely useful piece of apparatus has been devised by Prof. Lunge, and is described in the current number of the *Berichte*, by use of which all the troublesome reductions to standard temperature and pressure in the measurement of gas volumes may be avoided, the volume being actually read off corrected to 0° C. and 760 mm. pressure. The arrangement is at once simple and capable of adaptation to any form of gas apparatus. It consists essentially of three glass tubes, A, B, and C, arranged parallel to each other vertically, and all connected with each other below by means of a glass T tube and stout caoutchouc tubing. A is the measuring vessel, graduated in cubic centimetres; any gas measuring vessel, such as that of a nitrometer, or of a Hempel or other gas analysis apparatus, may be used for this purpose. It is closed at the top by the usual well-fitting stopcock, through which the gas to be measured is introduced in the ordinary manner. Below, the gas is enclosed by mercury which is poured down the tube C; Prof. Lunge terms this latter the pressure tube. The pressure tube is simply an ordinary straight glass tube of similar diameter and length to the measuring tube A, and open at the top. The tube B, called the reduction tube, is of about the same length, but of somewhat greater diameter in its upper half. This cylindrical expansion narrows again at the top, and terminates with a well-greased stopcock. A is firmly clamped to the stand, while B and C are held in spring clamps which permit of ready lowering or raising. The reduction tube B is then prepared as a reference tube, once for all, in the following manner. The stopcocks of A and B are opened, and mercury is poured down C until it rises nearly to the expanded portion of B. A drop of water is then introduced into B so that the enclosed air is saturated with aqueous vapour. The thermometer and barometer are next observed, and the apparent volume calculated of 100 c.c. of gas at 0° and 760 mm. A mark is then made upon the reduction tube B so that the volume of the tube between this mark and the stopcock is the

calculated apparent volume of the standard 100 c.c. The size of the tube is so arranged that this mark falls on the narrower portion of the tube, just below the expanded part. The pressure tube C is then raised or lowered until the mercury in B stands at the mark, when the stopcock at the top of B is closed. Thus a volume of air is enclosed which at 0° and 760 mm. and in the dry state would occupy exactly 100 c.c. In order to determine the corrected volume of a gas it is then only necessary to introduce it into the measuring tube A, allow it to cool to the temperature of the room, and then adjust B until the mark is a little higher than the mercury meniscus in A; C is next raised until the mercury in B rises to the mark, when B and C are finally simultaneously lowered until the level of the mercury in A and B is the same. The gas in A and the air in B are evidently equally compressed, and thus the volume read off upon the measuring tube A represents the corrected volume at 0° and 760 mm. The simplicity of the arrangement and the rapidity with which it can be worked are sure to recommend it for general use; and its applicability to the estimation of nitrogen in organic substances, which Prof. Lunge discusses in detail, will doubtless be especially appreciated by those who employ the volumetric method.

THE additions to the Zoological Society's Gardens during the past week include two Red Tiger Cats (*Felis planiceps* jv.) from Malacca, a —— Fish Eagle (*Polioaëtus ichthyaëtus*) from the Himalayas, deposited; a Gayal (*Bibos frontalis* ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on March 20 = 9h. 53m. 31s.

Name.	Mag.	Colour.	R.A. 1890.	Decl. 1890.

Remarks.

(1) This nebula is described in the General Catalogue as "Very bright; large; very much extended in a direction 45°; at first very gradually, then very suddenly much brighter in the middle to an extended nucleus." The spectrum of the nebula was observed by Lieut. Herschel in 1868, but his observations are not quite complete. He states that a continuous spectrum was suspected, and that there were probably no lines present. Further observations are obviously required.

(2) A star of Group II. Dunér states that the bands 2–8 are well seen, but that 4 and 5 are somewhat feeble. The spectrum is not strongly marked. The star is probably approaching the temperature at which the bands will be replaced by lines, and affords an opportunity of studying the order of the appearance of the lines.

(3) A star of the solar type (Gothard). The usual differential observations are required.

(4) A star of Group IV. (Gothard). The usual observations are required.

(5) One of the finest examples of stars with spectra of Group VI. Dunér states that the four bright zones and all the bands which he has numbered 1–10 are visible. In this star, band 6 is weaker than the other carbon bands. Band 5 is strong; 1, 2, and 3 are weaker; and 7 and 8 are visible with difficulty.

(6) This variable will reach a maximum on March 28. The period is about 146 days and the magnitudes at maximum and minimum 6·5–7·5 and 10–10·9 respectively (Gore). The spectrum is a remarkable one of the Group II. type, and the great range suggests the possible appearance of bright lines at maximum, as in R Andromedæ, &c., observed by Mr. Espin. Mr. Espin has noticed that in the variables, where F is very bright, the bright lines do not appear until some time *after* the maximum. It is therefore important to continue observations for a considerable period.

(7) No record of the spectrum of this variable appears to have been published. The period is about 176 days. The magnitude at maximum is 9–9·5, and that at minimum 13·5 (Gore). A maximum will be reached about March 23.

A. FOWLER.

THE MÉGUÉIA METEORITE.—This meteorite was observed to fall at Méguéia, in Russia, on June 18, 1889, and a short account of Prof. Simaschko's analysis of it is found in the current number of *L'Astronomie*. It is noted that the meteorite belongs to that remarkable division containing carbon in combination with hydrogen and oxygen. The meteorites of this class are Alais, 1806, Cold Bokkeveldt, 1838, Kaba, 1857, Orgueil, 1864, and Nogoya, 1880. The Méguéia meteorite is covered with a thin (0·5 mm.) crust, is black, partly dull and partly shiny, and somewhat friable. A microscopical examination showed dark grey specks distributed through the black mass, varying in size from a mustard-seed to a hemp-seed. These grey specks have a more or less chondritic structure, and are different in composition from the mass of the meteorite. Besides these chondrules, the greenish, semi-transparent particles of olivine are seen as in almost all other meteorites, whilst nickel-iron is disseminated through the mass in small grains, and occurs in a half-fused state on the crust. Account is also given of white angular scales, much resembling certain fossils, but this is not the first time that the chondrules with their eccentrically radiating crystallization have been mistaken for organisms. Like other carbonaceous meteorites, that of Méguéia has a bituminous smell.

THE VELOCITY OF THE PROPAGATION OF GRAVITATION.—M. J. Van Hepperger, in a paper read before the Vienna Academy of Science, has assigned an inferior limit to the velocity of propagation of gravitation. It results from this limit that the time taken by gravitation to travel the radius of the earth's orbit does not exceed a second.

THE VATICAN OBSERVATORY.—The work to be undertaken at this new Observatory will be in connection with meteorology, terrestrial magnetism, seismology, and astronomy. The astronomical portion will mainly be directed to the photography of the sun and other celestial bodies, and to take part in the construction of the photographic map of the heavens, under the direction of the International Committee.

DOUBLE-STAR OBSERVATIONS.—Mr. S. W. Burnham, of the Lick Observatory, gives his sixteenth catalogue of double-stars in *Astronomische Nachrichten*, Nos. 2956–57. The observations were made in May, June, and July 1889, and 62 new pairs have been discovered and measured during this period.

SUN-SPOT IN HIGH LATITUDES.—The *Comptes rendus* of the Paris Academy of Sciences for March 10 contains a short note by M. G. Dierckx, in which he states that he observed a sun-spot on March 4 in N. lat. 65°. If this were substantiated, it would be an almost unprecedented observation. But the photograph of the sun taken at the Royal Observatory, Greenwich, on that day, shows no trace of a spot in so high a latitude. A fine group did indeed appear on the sun on March 4, but its latitude was only 34°. This, however, is a very interesting circumstance, for though spots have been observed at considerably greater distances from the equator, they have usually been only small, and have lasted but a few hours, or two or three days at most. It would seem probable, therefore, this is the group which M. Dierckx observed, but that he made some error in determining its latitude.

GEOGRAPHICAL NOTES.

THE limits of the ever-frozen soil in Siberia are the subject of a paper by M. Yatchevsky, in the *Izvestia* of the Russian Geographical Society (vol. xxv. 5). It is now generally admitted that Karl Baer's criticism of Middendorff's measurements in the Sherghin shaft at Yakutsk—from which measurements Middendorff concluded that the depth of frozen soil at Yakutsk reaches 600 feet—are well founded. The walls of the shaft, which was pierced seven years before Middendorff came to Yakutsk, had cooled in the meantime through the free access of cold air, and therefore a smaller increment of increase of

temperature with depth was found by Middendorff than would have been found if the measurements had been made in a shaft immediately after its being pierced. Nevertheless, the fact of the frozen soil extending to a great depth, especially in the valley of the Lena, is not to be contested; nor can there be any doubt as to the extension of frozen soil over large parts of Siberia. M. Yatchevsky attempts to determine its limits from general considerations about the average yearly temperature of separate regions, and the thickness of their snow-covering; and he gives a map of the probable southern limits of the frozen soil in Siberia, which do not differ much from the yearly isotherm of -2° C. It must, however, be remarked that though the map approximately shows where the ever-frozen soil *may* be found beneath the thin layer of soil which thaws every summer, it ought not to be concluded that ever-frozen soil *will* be found everywhere within those limits. For instance, the granite rocks on the surface of the Vitrin plateau being immediately covered with immense marshes, the water from these marshes infiltrates into the rocks, and, while the marshes are covered during the winter with a crust of ice, their depths remain unfrozen. It may thus be considered certain that immense spaces will be found within the theoretical limits marked on the map, where no ever-frozen soil will be discovered. The Russian Geographical Society is sending out a series of questions, in the hope of obtaining accurate information, and it would be well if the same thing were done in Canada.

According to a letter from Iceland, dated Reykjavik, February 5, 1890, a translation of which is printed in the current number of the *Board of Trade Journal*, the population of Iceland during the four years from 1885 to 1888 inclusive has diminished by about 2400, the total number at the close of each of these years having been, in 1885, 71,613; in 1886, 71,521; in 1887, 69,641; and in 1888, 69,224. This diminution was greatest (1880) in 1887, the explanation for which may be sought in the enormous emigration to America which took place in that year. The diminution in the remaining years, though less sensible, must be attributed to the same cause, as in these years the number of births exceeded that of deaths. The chief diminution has been shown by the northern and eastern districts. The prefecture of Hunavatn in particular has fallen off in respect to inhabitants from 4800 in 1885 to 3785 in 1888. In Reykjavik, the capital, the population has risen from 3460 to 3599.

ATMOSPHERIC DUST.[1]

The infinitely small particles of matter we call *dust*, though possessed of a form and structure which escape the naked eye, play, as you are doubtless aware, important parts in the phenomena of nature. A certain kind of dust has the power of decomposing organic bodies, and bringing about in them definite changes known as putrefaction, while others exert a baneful influence on health, and act as a source of infectious diseases. Again, from its lightness and extreme mobility, dust is a means of scattering solid matter over the earth. It may float in the atmosphere as mud does in water, and blown by the wind will perhaps travel thousands of miles before again alighting on the earth. Thus Ehrenberg, in 1828, detected in the air of Berlin the presence of organisms belonging to African regions, and he found in the air of Portugal fragments of Infusoriæ from the steppes of America. The smoke of the burning of Chicago was, according to Mr. Clarence King (Director of the United States Geological Survey), seen on the Pacific coast.

Dust is concerned in many interesting meteorological phenomena, such as fogs, as it is generally admitted that fogs are due to the deposit of moisture on atmospheric motes. Again, the scattering of light depends on the presence of dust, and you may remember my showing you on a former occasion that beautiful experiment of Tyndall, illustrating the disappearance of a ray of light when made to travel through a glass receiver free from dust, whilst reappearing as soon as dust is admitted into the vessel. There is no atmosphere without dust, although it varies largely in quantity, from the summit of the highest mountain, where the least is found, to the low plains, at the seaside level, where it occurs in the largest quantities.

The origin of dust may be looked upon, without exaggeration, as universal. Trees shed their bark and leaves, which are powdered in dry weather and carried about by ever-varying currents of air, plants dry up and crumble into dust, the skin of man and animal is constantly shedding a dusty material of a scaly form. The ground in dry weather, high roads under a midsummer's sun, emit clouds of dust consisting of very fine particles of earth. The fine river and desert sand, a species of dust, is silica ground down into a fine powder under the action of water.

If the vegetable and mineral world crumbles into *dust*, on the other hand it is highly probable that dust was the original state of matter before the earth and heavenly bodies were formed; and here we enter the region of theory and probabilities. In a science like meteorology, where a wide door is open to speculation, we should avoid as much as possible stepping out of the track of known facts; still there is a limit to physical observation, and in some cases we can do no more than glance into the possible or probable source of natural phenomena. Are we on this account to give up inquiring for *causes*? This question I shall beg to leave you to decide, but where we have such an experienced authority as Norman Lockyer, I think the weight attached to possibilities and theories is sufficiently great to warant my drawing your attention for a few moments to the probable origin of the stars and of our earth.

I dare say many of you have read the interesting article in the *Nineteenth Century* of November last, by Norman Lockyer, and entitled "The History of a Star." The author proposes to clear in our imagination a limited part of space, and then set possible causes to work; that dark void will sooner or later be filled with some form of matter so fine that it is impossible to give it a chemical name, but the matter will eventually condense into a kind of dust mixed with hydrogen gas, and constitute what are called nebulæ. These nebulæ are found by spectrum analysis to be made up of known substances, which are magnesium, carbon, oxygen, iron, silicon, and sulphur. Fortunately for persons interested in such inquiries, this dust comes down to us in a tangible form. Not only have we dust shed from the sky on the earth, but large masses, magnificent specimens of meteorites which have fallen from the heavens at different times, some of them weighing tons, may be submitted to examination. From the spectroscopic analysis of the dust of meteorites we find that in addition to hydrogen their chief constituents are magnesium, iron, silicon, oxygen, and sulphur.

There are swarms of dust travelling through space, and their motion may be gigantic. We know, for instance, some stars to be moving so quickly that, from Sir Robert Ball's calculations, one among them would travel from London to Pekin in something like two minutes. From photographs taken of the stars and nebulæ, we are entitled to conclude that the swarms of dust meet and interlace each other, becoming raised from friction and collision to a very high temperature, and giving rise to what looks like a star. The light would last so long as the swarms collide, but would go out should the collision fail; or, again, such a source of supply of heat may be withdrawn by the complete passage of one stream of dust-swarms through another. We shall, therefore, have various bodies in the heavens, suddenly or gradually increasing or decreasing in brightness, quite irregularly, unlike those other bodies where we get a periodical variation in consequence of the revolution of one of them round the other. Hence, as Norman Lockyer expresses it clearly, "it cannot be too strongly insisted upon that the chief among the new ideas introduced by the recent work is that a great many stars are not stars like the sun, but simply collections of meteorites, the particles of which may be probably thirty, forty, or fifty miles apart."

The swarms of dust referred to above undergo condensation by attraction or gravitation; they will become hotter and brighter as their volume decreases, and we shall pass from the nebulæ to what we call true stars.

The author of the paper I am quoting from imagines such condensed masses of meteoric dust being pelted or bombarded by meteoric material, producing heat and light, which effect will continue so long as the pelting is kept up. To this circumstance is due the formation of stars like suns. Our earth originally belonged to that class of heavenly bodies, but from a subsequent process of cooling assumed its present character.

While apologizing for this digression into extra-atmospheric dust, I shall propose to divide atmospheric dust into *organic*, or *combustible*, and *mineral*, or *incombustible*. The dust scattered everywhere in the atmosphere, and which is lighted up in

[1] An Address delivered to the Royal Meteorological Society, January 15, 1890, by Dr. William Marcet, F.R.S., President.

a sunbeam, or a ray from the electric lamp, is of an organic nature. It is seen to consist of countless motes, rising, falling, or gyrating, although it is impossible to follow any of them with the eye for longer than a fraction of a second. We conclude that their weight exceeds but very slightly that of the air, and moreover, that the atmosphere is the seat of multitudes of minute currents, assuming all kinds of directions. Similar currents, though on a much larger scale, are also met with in the air. One day last June, from the top of Eiffel's Tower in Paris, I amused myself throwing an unfolded newspaper over the rail carried round the summmit of the tower. At first it fell slowly, carried away by a light breeze, but presently it rose, and, describing a curve, began again to fall. As it was vanishing from sight, the paper seemed to me as if arrested now and then in its descent, perhaps undergoing again a slight upheaval. Here was, indeed, a gigantic mote floating in the atmosphere, and subject to the same physical laws, though on a larger scale, as those delicate filaments of dust we see dancing merrily in a sunbeam.

I recollect witnessing at one of the Friday evening lectures of the Royal Institution in the year 1870 the following beautiful experiment of Dr. Tyndall, illustrative of the properties of atmospheric dust:—If we place the flame of a spirit-lamp or a red-hot metal ball in the track of a beam of light, there will be seen masses of dark shadows resembling smoke emitted in all directions from the source of heat. At first sight this appears as if due to the dust-particles being burnt into smoke; but by substituting for the spirit-flame or red-hot metal ball an object heated to a temperature too low to burn the motes, the same appearance of smoke is observed, hence the phenomenon is not owing to the combustion of the dust. The explanation, however, is obvious. The source of heat, by warming the air in its contact, and immediate proximity, made the air lighter and the motes relatively heavier, consequently they fell, and left spaces free from dust. These spaces in the track of the electric ray appeared dark, or looked as if full of a dense smoke, because the light of the ray could no longer be scattered in them from the absence of dust.

The motes were next examined by Tyndall, to determine whether they were organic or mineral. This was done by driving a slow current of air through a platinum tube heated to redness, and examining this air afterwards in a beam of light; it was then found to darken the ray, having lost the power of scattering light; therefore the dust had been destroyed or burnt by passing through the red-hot platinum tube, clearly showing its organic nature.

We breathe into our lungs day and night this very finely-divided dust, and yet it produces no ill effect, no bronchial irritation. Tyndall has again shown by the analytical power of a ray of light what becomes of the motes we inhale.

Allow me to return to the experiment with the red-hot metal ball placed in the beam of the electric light. Should a person breathe on the heated ball, the dark smoke hovering around it will at first disappear, but it will reappear in the last portions of the air expired. What does this mean? It means that the first portions of air expired from the lungs contain the atmospheric motes inhaled, but that the last portions, after reaching the deepest recesses in the organs of respiration, have deposited there the dust they contained.

It is difficult to say how much of the dust present in the air may become a source of disease, and how much is innocuous. Many of the motes belong to the class of *micro-organisms*, and the experiment to which we have just referred shows how easily these micro-organisms, or sources of infectious diseases, can reach the lungs and do mischief if they should find a condition of the body on which they are able to thrive and be reproduced. Atmospheric motes, although it has been shown that they are really deposited in the respiratory organs, do not accumulate in the lungs and air-passages, but undergo decomposition and disappear in the circulation. Smoke, which is finely-divided coal-dust, is clearly subjected to such a destructive process; otherwise the smoky atmosphere of many of our towns would soon prove fatal, and tobacco smoke would leave a deposit interfering seriously after a very short time with the phenomena of respiration.

Dust, however, in its physical aspect is far from being always innocuous, and, as you are aware, many trades are liable to suffer from it. The cutting of chaff, for horses' food, is one of the most pernicious occupations, as it generates clouds of dust of an essentially penetrating character. Those engaged in needle manufactures and steel-grinders suffer much from the dust of metallic particles. Stone-cutters, and workmen in plaster of Paris, coal-heavers, cotton and hemp spinners are also engaged in trades injurious to health because of the dust these men unavoidably work in. Those engaged in cigar and rope manufactures, or in flour-mills, hat and carpet manufacturers, are also liable to suffer for the same reason. A number of methods have been adopted, more or less successfully, to rid these trades of the danger due to the presence of dust. I shall not detain you on this subject, which would carry me too far, but merely bring to your notice the fact I observed many years ago, that charcoal has the power of retaining dust in a remarkable degree. I had charcoal respirators made of such a form as to cover both the mouth and nose, and containing about ½-inch thick of charcoal in a granular state. I could breathe through such a respirator in the thickest cloud of dust made by chaff-cutting without being conscious of inhaling any of the dust.

The subject of micro-organisms belongs to the science known as micro-biology. As meteorologists we are chiefly concerned with their distribution in the atmosphere. Micro-organisms are dust-like particles capable of cultivation or reproduction in certain media and at certain temperatures. If a particle of matter known to contain micro-organisms, also called *bacilli*, be placed on a clear surface of gelatine and maintained at a temperature favourable to its development, in a short time the gelatine will be found to contain a colony of those same *bacilli*. A fact so often stated as to become a medical truism is that there can be no infectious disease without the presence of the micro-organism special to that disease. Open cesspools, putrid meat or vegetable matter, accumulations of refuse, have no ill effects on health unless the micro-organisms of a certain disease, as those of typhoid fever or cholera, be present. On such foul decomposing matters these organisms thrive. They are reproduced with great activity, and become virulent in their effects.

Micro-organisms are scattered everywhere in the atmosphere. Dr. Miguel, at the Montsouris Observatory at Paris, has made an extensive inquiry into their distribution in air and water. In this country Dr. Percy Frankland has, with praiseworthy labour and perseverance, investigated the subject of micro-organisms, and ascertained their number in various localities. The result of his inquiry is that in cold weather, especially when the ground is covered with snow, the number of organisms in the air is very much reduced, and presents a very striking contrast with that found in warmer weather. The experiments made on March 9 show that during cold and dry weather, with a strong east wind blowing over London, a large number of micro-organisms may still be present in the air. It is particularly noticeable that even after an exceedingly heavy rain, and within a few hours afterwards, the number of micro-organisms in the air should be as abundant as usual. Taking an average of the experiments made on the roof of the Science Schools of the South Kensington Museum, the mean number of organisms found in 10 litres of air amounted to 35, while an average of 279 fell on one square foot in one minute. Other experiments made near Reigate and in the vicinity of Norwich present a marked contrast with those undertaken in the South Kensington Museum. There was a remarkable freedom from micro-organisms of the air collected on the heath near Norwich during the comparatively warm April weather, when the ground was dry. The air in gardens at Norwich and Reigate was richer in micro-organisms than that of the open country. Again, the number of organisms found in the air of Kensington Gardens, Hyde Park, and Primrose Hill was less than in that taken from the roof of South Kensington, but greater than in the country.

Experiments made in inclosed places, where there is little or no aërial motion, show the number of suspended organisms to be very moderate, but as soon as any disturbance in the air occurs, from draughts or people moving about, the number rapidly increases and may become very great. Experiments made in a railway carriage afford a striking example of the enormous number of micro-organisms which become suspended in the air when many persons are brought together.

Micro-organisms being slightly heavier than air, have an invariable tendency to fall, and on that account frequently collect on the surface of water; hence rivers, lakes, and ponds are constantly being thus contaminated. Micro-organisms in very pure water are not readily disposed to multiply, but traces of decomposing organic matter will induce their reproduction. One remarkable case occurs to me illustrating this fact. In 1884 a severe epidemic of typhoid fever broke out in the town of

Geneva, in Switzerland. The water of the lake in the harbour, which is surrounded by houses on three sides, was then examined by a distinguished micro-biologist, M. Fol, who discovered it to be full of micro-organisms; the water supplied to the town for drinking-purposes was taken from the River Rhone immediately as it flowed out of the harbour. The inquiry was pursued further, and it was found that just outside the harbour, on the surface of the water, there were still a number of micro-organisms, though less than in the harbour; but a few feet below the surface, say 3 or 4 feet, they had greatly diminished in number, indeed to such an extent that there were very few present. The obvious remedy was at once carried out. A wooden aqueduct was constructed, opening into the lake about 150 yards outside the harbour, and some 3 or 4 feet under the surface. As stated by Dr. Dunant, a Geneva physician who has given a very interesting account of this epidemic,[1] eighteen days after the source of the water-supply had thus been altered, a marked decline took place in the epidemic, and it was clearly being mastered. A similar epidemic due to a like cause occurred about the same time at Zurich.

There is one point connected with the properties of dust of organic origin which I think cannot fail to be of interest on the present occasion. I mean its inflammability, and its liability to explode when mixed with air. By *explosion* is meant that the propagation of flame by a very finely-divided material, such as coal-dust, mixed in due proportion with air, may proceed with a rapidity approaching the transmission of explosion by a gaseous mixture.

An interesting lecture was delivered on this subject at the Royal Institution, in April 1882, by Sir Frederick Abel, entitled "Some of the Dangerous Properties of Dust." The lecturer refers to instances of explosions in flour-mills, due in all probability to a spark from the grinding mill-stones, occurring in consequence of a deficient supply of grain to the stones.

Messrs. Franklin and Macadam, who investigated the subject, found that accidents of this nature were of frequent occurrence. In May 1878 a flour-mill explosion, quite unparalleled for its destructive effects, occurred at Minneapolis, Minnesota. Eighteen lives were lost, and six distinct corn-mills were destroyed. Persons who were near the scene of the calamity heard a succession of sharp hissing sounds, doubtless caused by the very rapid spread of flame through the dust-laden air of the passages inside the mill. The nearest mill to that first fired was 25 feet distance, and exploded as soon as the flames burst through the first mill. The explosion of the third mill, 25 feet from the second, followed almost immediately; and the other three mills, about 150 feet distance in another direction, were at once fired. The fire was attributed to a spark from friction of the mill-stones.

Coal-dust in coal-mines is a cause of accident from explosions, which has been closely investigated in this country, in Germany, and other mining districts. Sir Frederick Abel has given this subject especial attention, and brings it prominently forward in his valuable and exhaustive paper on "Accidents in Mines," read to the Institution of Civil Engineers in 1888. Some mines are, of course, more dusty than others, and coal-dusts are not all equally inflammable. That which is deposited upon the sides, top timbers, and ledges in a dry, dusty mine-way is much finer and more inflammable than the coarser dust which covers the floors. The lecture I have referred to alludes to the case of a considerable quantity of coal-dust accidentally thrown over some screens at a pit mouth bursting into flame as the dust cloud came into contact with a neighbouring fire, and burning a man very severely. There appears good ground for believing that fire may travel to a considerable extent through the workings of a mine from the ignition of coal-dust, as will be seen in the following account, extracted from Messrs. W. W. and J. B. Atkinson's book on "Explosions in Mines":—"An appalling accident happened at the Seaham Colliery, in the county of Durham, on September 8, 1880, at 2.20 a.m., causing the death of 24 men. An explosion occurred in the mine, and a loud report was heard at the surface, accompanied with a cloud of dust from the shaft, but no fire was seen. Owing to damage to the shaft it was more than twelve hours before a descent could be effected, and then a scene of destruction was witnessed by the explorers. Doors and air-crossings destroyed; tubs broken to pieces, and hurled one over the other; timber blown out, attended with heavy falls from the roof; and the bodies of men and horses in many cases terribly mutilated. The explosion was found to have extended over roads of an aggregate length of about 7500 yards, the greatest distance between the extreme points reached being about 3800 yards."

When discussing the cause of this terrible accident, Messrs. Atkinson remark that it was apparently impossible to account for the effects of the explosion on the assumption that it was due to fire-damp, as the presence of fire-damp was most unlikely to occur at any part at which the explosion could have happened; and therefore attention must be turned to coal-dust. There was coal-dust on all the roads traversed by the explosion, and there was coal-dust at the supposed point of origin. These facts are of striking significance. After the explosion, all parts of the mine in which its effects could be traced were covered on the bottom and on flat surfaces with a coating of fine dust, which, when examined under the microscope, appeared to have been acted on by great heat. This fine dust covered the surface for a depth of from $\frac{1}{8}$ to $\frac{1}{2}$ an inch and under. Dust of this kind was entirely absent on those roads over which the explosion had not extended. With reference to the original ignition, a shot had been fired apparently simultaneously with the explosion. The road at the place was of stone, and would probably be coated with the finest coal-dust; and, moreover, just above the spot where the fatal shot was fired were large baulks of timber, on which dust was plentifully stored. The shock caused by the explosion would throw the dust into the air, and the flame set fire to it. Thus initiated, the flame would extend through all the roads on which there was an uninterrupted supply of coal-dust to support it.

The second part of this address relates to inorganic or mineral dust. When on the Peak of Tenerife in 1878, engaged in a pursuit mostly of a physiological kind, I had occasion to use a very delicate chemical balance. My object was to determine the amount of aqueous vapour given out of the lungs while in the shallow crater at the summit of the Peak, 12,200 feet above the sea. The heat was intense, as the sun shed its nearly vertical rays at midday on the fine white volcanic sand spread over the floor of the crater. At various places rocks projected, covered here and there with crystals of sulphur, and so hot that the hand could scarcely bear coming in contact with them. Anticipating some difficulty in the use of the balance from the action of the wind, I had brought up with me a hamper and a blanket. After placing the hamper sideways, with the lid off, I proceeded, though not without some little trouble, to dispose the balance satisfactorily inside the basket; then, having thrown the blanket over the hamper, I stretched out at full length on the burning sand, nestling under the blanket, much as a photographer would cover himself and camera with a dark cloth. On trying to use the balance, it refused to act; its beam would not oscillate. A careful examination showed the instrument to be apparently in perfect order, when it occurred to me to wipe the knife-edges at the points of suspension of the beam and pans. The balance then worked quite well, though but for a few minutes only, again most provokingly declining to oscillate; indeed, it was only by constant wiping of the knife-edges that I succeeded with my experiment. The cause of my trouble was clearly the presence of very fine mineral dust in the air, of which my senses were utterly unconscious. Hence it is that extremely fine particles of mineral dust may exist in the atmosphere, while escaping detection by our senses, and such an occurrence is probably more frequent than generally thought.

Prof. Piazzi Smyth, while on the Peak of Tenerife, witnessed strata of dust rising to a height of nearly a mile, reaching out to the horizon in every direction, and so dense as to hide frequently the neighbouring hills. The Report of the Krakatão Commission of the Royal Society contains the following interesting account, p. 421 (Mr. Douglas Archibald's contribution to the Report):—"In 1881, Prof. S. P. Langley ascended Mount Whitney, in Southern California, with an expedition from the Alleghany Observatory; at an altitude of 15,000 feet his view extended over one of the most barren regions in the world. Immediately at the foot of the mountain is the *Inyo Desert*, and in the east a range of mountains parallel to the Sierra Nevada, but only about 10,000 feet in height. From the valley the atmosphere had appeared beautifully clear, but, as stated in Prof. Langley's own words, "from this aërial height we looked down upon what seemed a kind of level dust ocean, invisible from below, but whose depth was six or seven thousand feet, as the upper portion only of the opposite mountain range rose clearly out of it. The colour of the light reflected to us from

[1] "Epidémie de fièvre typhoide à Genève en 1884," par P. L. Dunant, *Revue Médicale de la Suisse Romande*, 1887.

this dust ocean was clearly red, and it stretched in every direction as far as the eye could reach, although there was no special wind or local cause for it. It was evidently like the dust seen in mid-ocean from the Peak of Tenerife—something present all the time, and a permanent ingredient of the earthy atmosphere."

Dust Storms.—These storms, as suggested by Dr. Henry Cook, from whose paper to the Quarterly Journal of the Royal Meteorological Society, in 1880, I am now quoting, may be considered under three heads, according to their intensity—atmospheric dust, dust columns, and dust storms. Dr. Cook, alluding to occurrences in India, observes that there are some days on which, however hard and violently the wind may blow, little or no dust accompanies it; while on others, every little puff of air or current of wind forms or carries with it clouds of dust. If the wind which raises the dust is strong, nothing will be visible at the distance of a few yards, the sun at noon being obscured. The dust penetrates everywhere, and cannot be excluded from houses, boxes, and even watches, however carefully guarded. The individual particles of sand appear to be in such an electrical condition that they are ever ready to repel each other, and are consequently disturbed from their position and carried up into the air.

Dust columns are considered by Dr. Cook as due to electrical causes. On calm, quiet days, when hardly a breath of air is stirring, and the sun pours down its heated rays with full force, little eddies arise in the atmosphere near the surface of the ground. These increase in force and diameter, catching up and whirling round bits of sticks, grass, dust, and, lastly, sand, until a column is formed of great height and considerable diameter, which usually, after remaining stationary for some time, sweeps away across country at great speed. Ultimately it loses gradually the velocity of its circular movement and disappears. In the valley of Mingochar, which is only a few miles in width, and surrounded by high hills, Dr. Cook, on a day when not a breath of air stirred, counted upwards of twenty of these columns. They seldom changed their places, and, when they did so, moved but slowly across the level tract. They never interfered with each other, and appeared to have an entirely independent existence.

Dr. Cook describes as follows a dust storm which took place at Jacobabad:—"The weather had been hot and oppressive, with little or no breeze, and a tendency for dust to accumulate in the atmosphere. On the evening of the storm heavy clouds gathered and covered the sky. About 9 p.m. the sky had cleared somewhat, and the moon shone. A breeze sprang up from the west, which increased and bore along with it light clouds of sand. At 9.30 p.m. the storm commenced in all its fury. Vast bodies of sand were drifted violently along. The stars and moon were totally obscured. It became pitch dark, and it was impossible to see the hand held close to the face. The wind blew furiously in gusts, and heaped the sand on the windward side of obstacles in its course. Lightning and thunder accompanied it, and were succeeded by heavy rain. The storm lasted about an hour, when the dust gradually subsided. The sky again became clear, and the moon shone brightly. The storm appeared to have entirely relieved the electrical condition of the atmosphere. A pleasant freshness followed, and the oppressive sensation before mentioned was no longer experienced. This, indeed, is the general effect of storms in Upper Scind. The air is cooled, the atmosphere cleared, and the dusty condition of the atmosphere which usually precedes them for several days completely disappears."

In the case of a memorable sand storm which occurred at Aden on July 16, 1878, and recorded by Lieutenant Herbert Russell, there was a remarkable play of light on the objects which remained within sight. The sudden darkness from the storm gave a peculiar and ghastly tint to the white sand and neighbouring plain, while the curling masses of sand drifted before the gale, resembling a dark yellow smoke. The varied lights, quickly changing, were curious and most grand; the sea a clear green, and Slave Island and Shum-Shum, usually of an arid brown colour, became of an ashy white.

In a dust storm I experienced myself at Luxor, on the Nile, the suffocating effect of the sand as it drove into the lungs and air passages was very trying. People rushed to the immediate river side, where some relief was found.

A book on "Whirlwinds and Dust Storms in India," by P. L. H. Baddeley, Surgeon, Bengal Army, 1860, gives some interesting information on the electrical character of dust storms and dust pillars. When at Lahore in 1847, this gentleman was desirous of experimenting on the electrical state of the atmosphere in a dust storm, and with this object he projected into the air, on the top of his house, an insulated copper wire fixed to a bamboo; the wire was brought through the roof into his room, and connected with a gold-leaf electrometer, a detached wire communicating with the earth. A day or two after, during the passage of a small dust storm, he observed the occurrence of vivid sparks from one wire to the other, and, of course, strongly affecting the electrometer. He subsequently witnessed at least sixty dust storms of various sizes, all presenting the same kind of phenomena.

Volcanic Dust.—This dust consists mainly of powdered vitrified substances, produced by the action of intense heat. It is interesting in many respects. The so-called ashes or scories shot out in a volcanic eruption are mostly pounded pumice, but they also originate from stones and fragments of rocks which, striking against each other, are reduced into powder or dust. Volcanic dust has a whitish-grey colour, and is sometimes nearly quite white. Thus it is that, in summer, the terminal cone of the Peak of Tenerife appears from a distance as if covered with snow; but there is no snow on the mountain at that season of the year; the white cap on the Peak is entirely due to pumice ejected centuries ago. It is probably to this circumstance that the island and Peak owe their name, as in the Guelph language the words *Tener Ifa* mean *white mountain*.

The friction caused by volcanic stones and rocks as they are crushed in their collision develops a mass of electricity which shows itself in brilliant displays of branch lightning darting from the edges of the dense ascending column. During the great eruption of Vesuvius, in 1822, they were continually visible, and added much to the grandeur of the spectacle. It not unfrequently happens that dust emitted from Vesuvius falls into the streets of Naples; but this is nothing in comparison with the mass of finely-powdered material which covered and buried the towns of Pompeii, Herculaneum, and Stabiæ in the year 79.

On this occasion, according to the younger Pliny, total darkness from the clouds of volcanic ashes continued for three days, during which time ashes fell like a mantle of snow all over the surrounding country. When the darkness cleared away, the calamity was revealed in all its awful extent, the three towns having disappeared under the showers of dust.

The eruption of Krakatão, a mountain situated on an island in the Straits of Sunda, exceeded, in all probability, in its deadly effects, and as a wonderful phenomenon of Nature, the outburst of Vesuvius in the year 69. The Krakatão Committee of the Royal Society have collected and published in their interesting Report particulars of that memorable eruption, all of them thoroughly authenticated and reliable. The following is extracted from a communication to the Report by Prof. Judd:—"On August 26, 1883, it was evident that the long-continued moderate eruptions of Krakatão had passed into the paroxysmal stage. That day, about 1 p.m., the detonations caused by the explosive action attained such a violence as to be heard at Batavia and Buitzsenborg, about 100 English miles away. At 2 p.m. Captain Thompson, of the *Medea*, then sailing at a point 76 miles east-north-east of Krakatão, saw a black mass like smoke rising into the clouds to an altitude which has been estimated at no less than seventeen miles (nearly six times the height of Mont Blanc)."

If this surmise be correct, some idea of the violence of the outburst can be formed from the fact that during the eruption of Vesuvius in 1872 the column of steam and dust was propelled to a height of from 4 to 5 miles only.

At 3 p.m. the explosions were loud enough to be heard 150 miles away. At Batavia and Buitzsenborg the noise is described as being like the discharge of artillery close at hand. Windows rattled, pictures shook, but there was nothing in the nature of earthquake shocks—only strong air vibrations.

Captain Wooldridge, of the *Sir R. Sale*, viewing the volcano at sunset on the 26th, describes the sky as presenting a most terrible appearance, the dense mass of cloud of a murky tinge being rent with fierce flashes of lightning. At 7 p.m., when from the vapour and dust clouds intense darkness prevailed, the whole scene was lighted up by electrical discharges, and at one time the cloud above the mountain presented the appearance of an immense pine-tree, with the stem and branches formed of volcanic lightning. The air was loaded with excessively fine ashes, and there was a strong sulphurous smell. The steamer *G. G. Loudon*, within 20 or 30 miles of the eruption, passed through a rain of ashes and small bits of stone.

Captain Watson, of the ship *Charles Bal*, at a spot about a dozen miles off the island, records the phenomena of chains of fire appearing to ascend between the volcano and the sky, while on the south side there seemed to be a "continual roll of balls of white fire." These appearances were doubtless caused by the discharge of white-hot fragments of lava rolling down the sides of the mountain. From midnight till 4 a.m. explosions continually took place, the sky one second being intense blackness, the next a blaze of fire.

All the eye-witnesses agree as to the splendour of the electrical phenomena. Captain Woolridge, viewing the eruption from a distance of 40 miles, speaks of the great vapour cloud resembling an immense wall, with outbursts of fork lightning, like large luminous serpents, rushing through the air. After sunset, this dark wall assumed the appearance of a blood-red curtain, with the edges of all the shades of yellow—the whole of a murky tinge, and attended with fierce flashes of lightning. It was reported from the *London* that lightning struck the mast-head conductor five or six times, and that the mud-rain which covered the masts, rigging, and decks was phosphorescent. The rigging presented the appearance of St. Elmo's fire, which the native sailors were busily engaged putting out with their hands, alleging that, if any portion found its way below, a hole would burst in the ship; not that they feared the ship taking fire, but they thought the light was the work of evil spirits, and that if it penetrated the hold of the vessel, the evil spirits would triumph in their design to scuttle the ship.

By these grand explosive outbursts the old crater of Krakatão was completely eviscerated, and a cavity formed more than 1000 feet in depth; while the solid materials thrown out from the crater were spread over the flanks of the volcano, forming considerable alterations in their forms.

The sea disturbance which accompanied the eruption of Krakatão was carefully investigated by Captain Wharton, Hydrographer to the Admiralty:—"The rush of the great sea wave over the land, caused by the violent abrasion in the crater, aided by the action on the water of enormous masses of fallen material, caused great destruction of life and poverty in the Straits of Sunda. By the inrush of these waves on land, all vessels near the shore were stranded, the towns and villages near the coast devastated, two of the lighthouses were swept away, and the lives of 36,380 of the inhabitants sacrificed. It was estimated that the wave was about 50 feet in height when it broke on the shore."

On the morning of the 27th, between 10 and 11 a.m., three vessels at the eastern entrance of the Straits encountered the fall of mingled dust and water, which soon darkened the air, and covered their decks and sails with a thick coating of mud. Some of the pieces of pumice falling on the *Sir R. Sale* were said to have been of the size of a pumpkin. All day on the 27th, the three vessels were beating about in darkness, pumice-dust falling upon them in such quantities as to employ the crew for hours in shovelling it from the decks and in beating it from the sails and rigging. At Batavia, 100 miles from Krakatão, the sky was clear at 7 a.m., but at 11 a.m. there fell a regular dust-rain; at 11.20 complete darkness pervaded the city. The rain of dust continued till 1, and afterwards less heavily till 3 p.m.

The speed and distance attained by the pumice ejected from the volcano may be conceived from the fact stated in Mr. Douglas Archibald's contribution to the Report, that dust fell on September 8, more than 3700 English miles from the seat of the eruption.

The great mass of the pumice thrown out during the eruption presented a dirty greyish-white tint, being very irregular in size. It was undoubtedly due to the collision of fragments of pumice as they were violently ejected from the crater; the noise produced was even more striking than the sound of the explosion.

The dust ejected from Krakatão did not all fall back at the same time upon the sea and earth; as the lightest portions formed into a haze, which was propagated mostly westward. Mr. Archibald states in the Report that most observers agree upon considering this haze as the proximate cause of the twilight glows, coloured suns, and large corona, which were seen for a considerable time after the eruption. The haze was densest in the Indian Ocean and along the equatorial belt, and was often thick enough to hide the sun entirely when within a few degrees from the horizon.

And now, ladies and gentlemen, I must bring this address to a conclusion, and thank you for having followed me over a long, dusty track. I hope I have succeeded in showing that infinitely small objects, no larger than particles of dust, act important parts in the physical phenomena of Nature, just as small and apparently unimportant events occasionally lead to others of the greatest magnitude.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 6.—"The Cranial Nerves of the Torpedo" (Preliminary Note). By J. C. Ewart, M.D. Communicated by Prof. M. Foster, Sec. R.S.

The cranial nerves of the torpedo agree in their general arrangement with those of the skate.[1] The ophthalmicus profundus occupies the usual position, but its ganglion lies in close contact with the Gasserian, and not on a level with the ciliary ganglion. The trigeminus has the usual distribution, for, notwithstanding the statements in the most recent text-books,[2] the trigeminus sends no branch to the electric organ. The facial complex includes the superficial ophthalmic, the buccal, and the hyomandibular nerves, all of which have the same distribution as the corresponding nerves in the skate; but the hyomandibular includes or is accompanied by a large bundle of nerve fibres which supply the anterior and inner portion of the electric organ. This large nerve cord (the first electric nerve) has hitherto almost invariably[3] been described as a branch of the trigeminus. When traced backwards, it is found to spring from the anterior portion of the electric lobe.

The glossopharyngeus, a slender nerve in the skate, is represented in the torpedo by a thick cord which escapes by a large foramen in the outer wall of the auditory capsule. This large nerve consists of two portions, one of which is small and completely covered by the large superficial division. The small deep division, which in its course and distribution closely resembles the glossopharyngeal in the skate, presents on leaving the auditory capsule a distinct ganglionic swelling, beyond which it breaks up into the branchial and other branches. The large superficial division emanates from the electric lobe behind the origin of the first electric nerve, and at once runs outwards to reach and supply the majority of the columns of the anterior half of the electric organ.

The vagus complex consists of the nervus lateralis, the nervus intestinalis, and of five branchial nerves, of which the two anterior are accompanied by the third and fourth electric nerves. The nervus lateralis, lying superficial to all the other nerves, arises on a level with the root of the glossopharyngeus, and then curves backwards dorsal to the posterior electric nerve to reach the canal of the lateral line. Shortly after leaving the cranium it presents a distinct ganglionic swelling, which is crowded with large cells. The four branchial nerves for the four vagus branchiæ, the slender filament which represents a sixth branchial nerve, and the intestinal nerve lie at first in contact with each other under cover of the third and fourth electric nerves. When the branchial and intestinal nerves are carefully examined, they are found to present four, sometimes five, ganglionic enlargements, and in addition ganglionic cells can sometimes be detected at the proximal end of the slender sixth branchial nerve. The third and fourth electric nerves lie over and are especially related to the second and third branchial nerves. These large electric nerves spring from the posterior half of the electric lobe, and find their way outwards partly behind and partly under the auditory capsule, to terminate in the posterior half of the electric organ.

It thus appears that all the electric nerves spring from the electric lobe, that the first accompanies the hyomandibular division of the facial complex, the second the glossopharyngeus, and the third and fourth the first two branchial nerves of the vagus complex. It remains to be seen whether the electric nerves have been derived from motor branches of the nerves with which they are respectively associated by an enormous increase in the number of their fibres, as the muscular fibres were gradually transformed into electric plates.

Physical Society, Feb. 21.—Prof. G. Carey Foster, F.R.S., Past-President, in the chair.—The following communications were read:—On a carbon deposit in a Blake telephone trans-

[1] Ewart, "On the Cranial Nerves of Elasmobranch Fishes," Roy. Soc. Proc., vol. 45, 1889.

[2] *E.g.*, McKendrick, "Text-book of Physiology," 1888, and Wiedersheim, "Grundriss der vergleichenden Anatomie," 1888.

[3] Fritsch is the only author I am acquainted with who does not describe the first electric nerve as a branch of the trigeminus, "Untersuchungen ueber den feineren Bau des Fischgehirns," Berlin, 1878.

mitter, by Mr. F. B. Hawes. The author exhibited photographs of the interior portions of the transmitter on which the deposit had taken place. These portions consist of a metal diaphragm, a highly-polished carbon button, and a platinum contact piece carried by a German silver spring placed between them. The diaphragm presented a mottled appearance due to the deposit, but the part which had been behind the German silver spring seemed comparatively clean. The deposits on the carbon button and German silver spring were much less dense than that on the exposed parts of the diaphragm, and the space near the point of contact between the platinum and carbon was free from deposit. The deposit was fairly adherent, some rubbing being necessary to remove it, and on examination under the microscope particles of copper and metallic crystals could be seen. The author believes the deposit due to some kind of bombardment of carbon particles, but was unable to say why it should occur, or why the varnished diaphragm should receive the greater deposit although it was further from the carbon than the German silver spring. Mr. C. V. Boys said the photographs reminded him of a phenomenon he observed some time ago on a glass sheet against which one terminal of a dry pile had been resting for some weeks. Just as on the carbon button, the glass near the point of contact was clean and had a comet-shaped deposit formed around it. He could offer no explanation of the appearance.—The geometrical construction of direct-reading scales for reflecting galvanometers, by Mr. A. P. Trotter. In a recent paper on galvanometers, by Prof. W. E. Ayrton, F.R.S., T. Mather, and Dr. W. E. Sumpner, read before the Society, the opinion was expressed that proportionality of scale reading to current was very desirable, and the present paper shows how to bend a scale of equal divisions so as to give the required proportionality. Suppose the currents required to produce several deflections have been experimentally determined. A full-size plan of the scale is then drawn, and radial lines from the points on the scale at which the observations were taken are drawn towards the centre of the mirror. Let these radii be numbered 0, 1, 2, 3, &c., commencing from zero azimuth. According to the procedure recommended, distances proportional to the several current strengths are marked off along the edge of a strip of paper, a few inches being left over at each end. Call the marks *a*, *b*, *c*, *d*, &c., *a* being the zero point. Two points on the radii 0, 1, and equidistant from the mirror are now found such that the distance between them is equal to that between *a* and *b* on the strip, and the points marked by fine needles stuck in the board. The zero end of the strip is now fixed so that the marks *a* and *b* lie against the needles, and the strip is swept round until the mark *c* coincides with the radius 2, where also a needle is placed. Repeating the process gives a series of points which on being joined form part of a polygon. A line can then be drawn between the inscribed and circumscribing curves which has the same length as the sum of the straight lines, and this is the curve to which the original scale may be bent so as to give proportional readings. Diagrams showing such curves, constructed from the calibrations of instruments given in the paper above referred to, accompany the paper. The author showed that a family of curves may be drawn, each of which satisfies the required condition. Of the two limiting curves, one is tangential to the usual scale line at zero azimuth, and the other passes through the vertical axis of the mirror. The flattest of the various curves is generally the most convenient. Mr. J. Swinburne asked whether good definition could be obtained when such curved scales not equidistant from the mirror were used, and also whether it was not easier to divide a flat scale unequally so that the readings are proportional to the current. Mr. Trotter, in reply, said Dr. Sumpner thought there would be no difficulty as regards definition with the flat curves shown. He (Mr. Trotter) also added that a curved scale might be advantageous in reading the deflections from one side of a table, as the more distant part of the scale could be more nearly perpendicular to the line of sight. For such an arrangement, however, a parallel beam of light would be required.—A parallel motion suitable for recording instruments, by Mr. A. P. Trotter. This is a modification of Watt's parallel motion, in which the two fixed centres are on the same side of the line described by the "parallel point." The arrangement consists of two vibrating arms, one of which is twice the length of the other, and whose outer ends are jointed respectively to the middle and end of a short lever; the free end of the latter describes an approximate straight line. The motion was arrived at by considering the curve traced out by a point on the radius of a circle, such that its distance from the circumference measured towards the centre is equal to the radial intercept between the circle and a tangent line. The equation to the curve is $r = 2 - \sec\theta$ (conchoid of Nicomedes) and the radius of the osculating circle at the point where the intercept is zero is given as half that of the initial circle. This osculatory circle, the author finds, practically coincides with the curve over a considerable angle (40°), and thus may replace this part of the curve; hence the motion. The author thinks the motion will be useful for recording barometers, ammeters, and voltmeters, as it is more compact than that of Watt, and needs no fixed point beyond the straight path.—Owing to the absence of Prof. S. P. Thompson, his paper on Bertrand's refractometer was not read.

Linnean Society, March 6.—Mr. Carruthers, F.R.S., President, in the chair.—Mr. Thomas Christy exhibited a dried specimen of *Picramnia antidesma*, the plant from the bark of which a medicine, known as *cascara amarya*, a useful alterative in diseases of the blood and skin, is believed to be prepared.—Mr. J. E. Harting exhibited a series of horns of the American Prongbuck (*Antilocapra americana*), to illustrate the mode in which the shedding and new growth of horn is effected in this animal.—A paper was read by Mr. D. Morris, on the production of seed in certain varieties of the sugar-cane (*Saccharum officinarum*). It was pointed out that, although well known as a cultivated plant, the sugar-cane had nowhere been found wild; nor had the seed (*caryopsis*) been figured or described; it being the generally received opinion that, having been propagated entirely by slips, or cuttings, it had lost the power of producing seed. Spikelets, however, received at Kew, had been carefully examined, and the seed found, which was now for the first time exhibited by Mr. Morris. He anticipated that, by cross-fertilization and selection of seedlings, the sugar-cane might be greatly improved, and much importance was attached to the subject, as it opened up a new field of investigation in regard to sugar-cane cultivation. Mr. J. G. Baker and Mr. Christy concurred.—A paper was then read by Mr. Spencer Moore, on the true nature of *callus*; Part 1, the vegetable-marrow and *Ballia callitricha*. It was shown that the *callus* of sieve-tubes of the vegetable-marrow gives marked proteid reactions; and since it is dissolved in a peptonizing fluid there can be no doubt of its being a true proteid, and not a kind of starchy mucilage, as is usually supposed. The "stoppers" of *Ballia* also yield proteid reactions, but inasmuch as they resist gastric digestion, the substance cannot be a true proteid, and may perhaps be allied to lardacein. Mr. Moore maintained the view of Russow, Strassburger, and others—that *callus* is deposited upon the sieve—to be correct in the case of the vegetable-marrow; since a peptonizing fluid clears the sieve-plates and leaves them in their pristine condition, which would not be the case if *callus* were formed by a swelling up of the sieves. A discussion followed, in which Dr. F. W. Oliver, Dr. D. H. Scott, Prof. Reynolds Green, and Mr. George Murray took part.

Zoological Society, March 4.—Prof. W. H. Flower, F.R.S., President, in the chair.—The Secretary read a report on the additions that had been made to the Society's Menagerie during the month of February 1890.—Mr. F. E. Beddard exhibited and made remarks on some living specimens of an Indian Earthworm (*Perichæta indica*), obtained from a greenhouse in Scotland.—Mr. A. Thomson exhibited a series of insects reared in the Insect House in the Society's Gardens during the past year, and read a report on the subject. Particular attention was called to specimens of a South African Mantis (*Harpax ocellata*) and of a Canadian Stick Insect (*Diaphemora femorata*).—Mr. Henry Seebohm read a paper on the classification of birds, being an attempt to diagnose the sub-classes, orders, sub-orders, and some of the families of existing birds. The characters upon which the diagnoses were based were almost entirely derived from points in the osteology, myology, and the pterylosis of the groups diagnosed.—A communication was read from Mr. T. D. A. Cockerell, describing some Galls from Colorado, of which specimens were transmitted for exhibition.

Edinburgh.

Royal Society, February 28.—Sir Douglas Maclagan, Vice-President, in the chair.—Prof. Rutherford communicated a paper on the structure and contraction of striped muscular fibre of crab and lobster.—Prof. Haycraft read a paper on the histology, functions, and development of the carapace of the Chelonia, and also another paper on the rate at which muscles contract when the motor paths are stimulated by interrupted electrical currents.

March 3.—Sir W. Thomson, President, in the chair.—Prof. Tait communicated a note on ripples in a viscous liquid. He investigates in it the motion of a continuous set of ripples, and discusses the effects of gravity, surface-tension, surface-stiffness, and viscosity.—Dr. Thomas Muir communicated a paper by Mr. D. Maver, on a geometrical method based on the principle of translation.—Prof. J. Stuart Blackie read a paper on the phases of the living Greek language.

PARIS.

Academy of Sciences, March 10.—M. Hermite in the chair.—Note on the life and works of George Henry Halphen, by M. Emile Picard.—On the phenomena seen about the sun on March 3, 1890, by M. A. Cornu. Halos and parhelia were seen about the sun on this date, and observations of the aqueous bands of the solar spectrum made at the time when the first halo of 22° appeared, showed that warm and moist currents existed in the higher regions of the atmosphere in spite of the exceptional cold (– 11° C.) at Paris.—Thermal researches on the allotropic modifications of arsenic, by MM. Berthelot and Engel. The amount of heat evolved on treatment with bromine and water was found to be nearly the same in both the forms; arsenic, in this respect, behaving like carbon.—Second note on the absorption of atmospheric ammonia by soils, by M. H. Schlœsing. From the experiments described in this and the previous note, the author finds that calcareous, acid or neutral, dry or wet soils, absorb atmospheric ammonia. Moist earth, however, favours the fixation of ammonia, and dry earth retards it.—The muscular and elastic elements of the retrolingual membrane of the frog, by M. L. Ranvier. The problems investigated are: the attachment of the elastic fibres to the muscular bundles, and whether a fibril terminates in a thick or thin disc or a clear space, all of which occur in the muscular bundles.—On the microbes of acute osteomyelites called infectious, by MM. Lannelongue and Achard.—Study of the errors of observation, by M. J. E. Estienne.—Sun-spot in very high latitude, by M. Dierckx. To this note we refer elsewhere (p. 472).—On Stirling's formula, by M. E. Rouché.—On regular surfaces which pass through a given curve, by M. Ch. Bioche.—On the compounds of phosphoretted hydrogen and ammonia with boron chloride and silicon hexachloride, by M. A. Besson.—Note on the compounds of the metals of the alkalies with ammonia, by M. J. Moutier.—On the estimation of free halogens and of iodides in presence of chlorine and bromine, by M. P. Lebeau. Iodine is estimated by liberation from its compound in aqueous solution by a standard solution of bromine, the iodine being dissolved out from the water by CS_2 as soon as liberated: the end of the reaction is indicated by the decoloration of the supernatant aqueous solution, to which a few drops of indigo solution has been previously added.—On the formation of thiosulphate of lead, note by M. J. Fogh.—Decomposition of thiosulphate of lead by heat. Trithionate of lead, by the same author. It is shown that, by the prolonged action of boiling water, thiosulphate of lead decomposes according to the equation $2PbS_2O_3 = PbS + PbS_3O_6$.—On a new iodide of bismuth and potassium, M. L. Astre.—Note on the molecular increase of dispersion of saline solutions, by MM. Ph. Barbier and L. Roux. If the constant K given in a previous communication be multiplied by the molecular weight of the dissolved salt, what the authors term the molecular increase of dispersion is obtained. MK for chlorides of the type MCl is shown to have the mean value 0·020, for chlorides MCl_2 the mean value is 0·044.—Researches upon the application of measurements of the rotatory power to the determination of compounds resulting from the action of malic acid upon the neutral molybdates of lithium and magnesium, by M. D. Gernez.—The volumetric estimation of tannin, by M. E. Guenez.—Estimation of acetone in methyl alcohol and in the raw methyl alcohol used for methylation, by M. Léo Vignon.—On the diminution of fermenting power of the ellipsoidal wine-yeast, in presence of salts of copper, by M. A. Rommier.—On a Coleopterous insect attacking the vine in Tunis (*Ligniperda francisca*, Fabricius), by M. A. Laboulbène.—The preparation of crystallized basic nitrate of copper and its identification with gerhardtite, by M. L. Bourgeois.

BERLIN.

Meteorological Society, February 11.—Prof. Schwalbe, President, in the chair.—Dr. Danckelmann spoke on the meteorological conditions which exist on the Gold and Slave Coast. General observations had been started in New Guinea, but were soon reduced to observations of rainfall only; during the years 1886 to 1889, they had yielded some interesting results on the connection between rainfall and the direction of the monsoons and trade-winds. No trustworthy data are as yet to hand of the meteorological conditions of Southern Africa, Cameroon, and East Africa, but, on the other hand, there is a mass of material accumulated at many stations on the Guinea coast. From the latter it appears that the atmospheric pressure varies but slightly, and shows a maximum in July and August. In Bismarckburg the wind blows from the north and north-east from the Sahara in December, January, and February; in June, July, and August it blows west and south-west. Variations of temperature are but slight, presenting a maximum in December to February, and a minimum in July and August. The amount of rainfall is very variable, being, in some places, as low as 575 mm. per annum; in others, 1000, 1500, or even 3500. The speaker concluded by describing the climatic conditions of this region, pointing out that they may be explained with reference to the contiguity of the Sahara Desert.—Dr. Eschenhagen gave a detailed description of the Magnetic Observatory at Potsdam, dealing with its structural arrangements and the internal location of the instruments. While exhibiting the photographically recorded curves of the previous fortnight, he dealt with the breaks in these which result from any more than usually severe shock of earthquake. These he attributed to purely mechanical causes rather than to magnetic, basing his views on observations of the movement of the surface of mercury at the time. He pointed out that the opposite view, urged by French meteorologists, as based upon observation of a copper rod with a bifilar suspension, is inconclusively supported by such observations, inasmuch as the equilibrum of a copper rod is relatively stable, while that of a bifilar magnet is unstable.—The President referred, in conclusion, to the loss which meteorology had sustained in the death of Buys Ballot.

Physiological Society, February 14.—Prof. du Bois Reymond, President, in the chair.—Prof. Zuntz gave an account of experiments conducted in his laboratory by Dr. Katzenstein, on the influence of bodily labour on the metabolism of man. After giving an historical *résumé* of previous researches, he described the methods employed in the present research. The experiments were conducted in a very convenient form of respiration-apparatus, the analysis of the gases being made by Hempel's method. Great stress was laid on the accurate determination of the work done; the latter consisted in either turning a wheel against a graduated resistance, or else in motion on either a plane or inclined surface. In the latter form of work an apparatus was used which had previously been employed in experiments on a horse. The oxygen consumed in each experiment was taken as a measure of the metabolism. It was found that this was permissible, from the fact that the respiratory quotient was observed to be constant during the three conditions of rest, walking, and climbing. From this it appeared that the energy required for any given work was the outcome of the union of oxygen and carbon in the formation of carbonic acid gas. The increased respiratory interchange which accompanied any extra work fell to the normal some two or three minutes after the work ceased. In each experiment the distance covered and height through which the body was raised was measured in kilogram-metres; the oxygen simultaneously absorbed was determined, and from this the amount of oxygen which would have been absorbed if no work had been done was subtracted, so that the amount of oxygen required for the given work was obtained. It was found that, as in Smith's experiments, the metabolism might be increased to two or three times the normal during work. The experiment was then repeated, employing a different rate of motion and steepness of ascent, so that it was readily possible to calculate the oxygen, in cubic centimetres, required for a progression of one metre or the raising of one kilogram; the former was then reduced to a unit of one kilogram of body-weight. The result obtained from the person on whom most of the experiments were made was that the moving of one kilogram of body-weight over one metre of space on the level involved a consumption of 1·11 c.c. of oxygen, and for the raising of one kilogram through one metre, a consumption of 1·438 c.c. In conclusion, the speaker drew some interesting comparisons between the results of these experiments and those previously made on a horse.—Dr. Benda exhibited several preparations of sense-organs of mammals; and Dr. Katz showed some specimens of the organ

of Corti.—Dr. Hausemann spoke on unsymmetrical karyokinesis met with in epitheliomata. Ordinarily the chromatin-filaments divide into two equal parts, but in cancer-cells they do not, and from this results the polymorphism of the nuclei.

Physical Society, Febuary 21.—Prof. du Bois-Reymond, President, in the chair.—Prof. von Bezold made a short speech in memory of Buys Ballot, pointing out with chief prominence that he was the first to draw attention to the necessity of co-operation between the meteorologists of different nations, and that he had been chiefly instrumental in establishing the existing International Meteorological Congress. He further showed that Buys Ballot was the first to give a survey of the meteorological conditions existing simultaneously at different places on the earth's surface, the pioneer in the production of the synoptic charts which are now published (see *Poggendorff's Annalen* for 1847), and the first to thoroughly grasp and state with precision the difference between weather and climate.—Dr. E. Pringsheim spoke on Kirchoff's law and gaseous radiation. During the experimental verification of the above, the speaker was chiefly interested in the behaviour of gases and vapours, and selected for his experiments sodium vapour. It was impossible to obtain any answer to the question "Does a gas acquire the power of emitting light-rays when its temperature is raised?" by the mere introduction of sodium or its salts into the non-luminous flame of a Bunsen burner, since it was not possible to exclude the occurrence of chemical changes during such an experiment. Thus he employed rather the method of Lockyer, Liveing, and Dewar, heating the metal in a sealed tube. In this way he verified the appearance of the bright emission-line and of the absorption-line of sodium. The lowest temperature at which they make their appearance was determined and measured thermo-electrically, but the speaker did not deduce any absolute value from his data. He further considered that the radiation of gases when heated is not yet definitely proved, since the nitrogen in which he heated the sodium contained minute traces of oxygen, and the method he employed for closing the ends of his tube permitted of the probable entry of small quantities of air. He had, therefore, additionally made experiments with thallium, and on the introduction of air into the metallic vapours; these experiments yielded a distinctly affirmative answer to the original question, but require further extension. So also do some experiments on the occurrence of a fluted spectrum of sodium, which the speaker had made during the course of the above work.

DIARY OF SOCIETIES.

THURSDAY, MARCH 27, 1890.

A SOUTH LONDON POLYTECHNIC.[1]

SOME little time ago we expressed our views on the general scheme put forward by the Charity Commissioners for the establishment of Polytechnics (we must use the word, however inapplicable) in various parts of London. Since then we have received a copy of the architect's report on the requirements of a Technical Institute for Battersea. It may be well to recall to the minds of readers the main features of the proposed scheme. The Polytechnic in Regent Street, and the People's Palace at Mile End, are to receive large endowments to enable them to continue and develop the work on which they are already engaged, a large sum is to be given to found a City Polytechnic, and series of three new Institutes are to be established in various parts of South London; whilst others, at present more or less shadowy and prospective, are talked of for other parts of the metropolis.

Of the three new Institutes, the plans for which may be said to be in an advanced condition, two will be housed in buildings already established. The Goldsmiths' Company have bought the Royal Naval School at New Cross, and are adapting and altering it so as to be ready to be opened for its new purpose in October next. The premises of the Borough Road Training College have been secured for the second of the Institutes, which is probably to be partly endowed by the Ironmongers' Company. The scheme in this case is not, we believe, yet published, and some delay may take place; but, if all goes smoothly, this Institute also may be ready to begin work before very long.

The third of the proposed South London Polytechnics is the Battersea Institute, for which we have received the draft plans. Here there is no existing building to be adapted. Everything must start *de novo*, and only the limits of the funds at their command, and their uncertainty as to the future tastes and wants of the district, need restrict the trustees in their efforts to make the Institute in every way worthy of its purpose.

And here we may at the outset congratulate the trustees on the mode in which they have determined to proceed. They have intrusted to Mr. Rowland Plumbe the task of visiting other technical schools, obtaining necessary information, and preparing a detailed statement of the requirements of the Battersea Institute, and have since circulated his draft Report among various experts, with requests for criticisms and suggestions. The plans with which the Report is illustrated are not intended to be in any way final, but merely to suggest the nature of the requirements of the Institute to the architect, whoever he may be, who is ultimately selected to design the building. It is clear that no stone will be left unturned, so far as the Committee are concerned, to make the Battersea Institute a model Polytechnic.

We may congratulate the Committee on another matter. In our former article we pointed out the inexpediency of attempting too much at once, while the whole question of the future of Polytechnics is in an experimental stage. Since then, Sir Bernhard Samuelson and other members of the Executive Committee of the Technical Association have publicly impressed similar views upon the Vice-President of the Council, into whose hands the Commissioners' scheme has now passed. We are, therefore, glad to see that Mr. Plumbe expressly states that his plans are drawn up so that the proposed building may be gradually constructed as the need arises; and though he does not conceal his own desire to have the whole building erected at once, we are glad to learn that the Committee have decided to let the institution grow as the number of students increases, and not to erect a great shell until they see more clearly the extent of the demand which it is to supply. We gather further that the sum required for the endowment of the Institute is not yet complete, and we may take it for granted that no attempt will be made to start operations until this necessary preliminary step is completed. Thus those who are anxious that the whole scheme for Polytechnics should not be imperilled by hastily founding too many at once before one new Institute has been made a success, may feel assured that the necessary interval which must elapse before the foundation-stone of the Battersea Institute can be laid will give some further opportunity to the promoters to profit by the experience which accumulates every day of the working of similar institutions elsewhere.

To quote Mr. Plumbe's Report, "The combined form of Institute . . . is a growth almost of the present day, and the subject as now presented is, with the hereinafter mentioned exception, comparatively new and *without precedent.*" The exception referred to is Mr. Hogg's Polytechnic, and as this is the product of the gradual growth of seventeen years, the argument for going "slow and

The promoters of the Goldsmiths' Institute at New Cross are, we understand, equally alive to this necessity.

Mr. Plumbe has made inquiries, for the purpose of his Report, into the nature of the industries of Battersea, and has visited several of the chief Technical Institutes in London, from the Bow and Bromley Institute up to the Central Institution of the City and Guilds Institute. He might, perhaps, with advantage have extended his visit to some of the more important provincial centres, which in some ways offer examples which are not to be found in the metropolis of the kind of equipment required for a popular technical school. London has long been behindhand in the matter, except for the higher Colleges at South Kensington, which are intended to serve a purpose so different that their example may be disregarded. There are, indeed, the two existing Polytechnic Institutes, and apparently Mr. Plumbe has derived from them almost all his information as to the requirements of the Battersea Institute. The Regent Street Polytechnic he considers "most undoubtedly must serve as a model to all succeeding institutions." He presumes that the Committee will "follow to some extent the curriculum of study adopted at Mr. Quintin Hogg's Polytechnic and the People's Palace."

Without in any way challenging these conclusions, it is only fair to point out that the first-hand inquiries on which they are based are mostly derived from these very

[1] "South London Polytechnic Institutes—Report on Requirements for the Battersea Institute." By Rowland Plumbe, F.R.I.B.A.

institutions. Now it is important that in a new departure like that which it is proposed to make at Battersea we should not blindly follow in the rut of any one existing institution, and the only way to avoid this is to profit by the experience of other technical institutes in various parts of the country. Mr. Plumbe quotes the Report (now nearly six years old) of the Royal Commission on Technical Instruction, but many of the more important provincial schools have sprung up since that date, and the Commission on Elementary Education to which he refers only dealt with elementary schools. He is consequently led to the very doubtful conclusion that provincial schools offer no example for London because of the "thoroughness and great cost of the education given (which further required the whole time of the pupils for a number of years)." "I have not," he continues, "thought it necessary to spend any further time on the examination of buildings of this character, particularly as I found those of most experience with whom I conferred on the subject were distinctly of my opinion."

Who these experts were we are not told, but the above remarks are scarcely applicable to such technical schools as those at Bradford, Huddersfield, Keighley, Manchester, Bristol, and other large centres, which are doing for the artisan population of those districts much the same service as is expected from the Battersea Institute.

Whether instruction be elementary or advanced, whether it be intended for masters or for workmen, it ought to be "thorough," and thoroughness implies to some extent costliness. "To educate the industrial classes on a large scale at a comparatively nominal cost" is an attempt which looks better on paper than in practice.

And this brings us to the question of the financial aspect of the scheme. Mr. Plumbe states that his estimate of the cost of a given amount of accommodation is based on a memorandum by Mr. H. Cunynghame, in which he calculates that the building, including land, &c., ought to be erected and fitted up for £11 per student or member and that the cost of annual maintenance, in addition to fees and grants, will amount to 15*s*. per head per annum. This estimate is naturally considered by Mr. Plumbe to be "moderate in the extreme." It is much to be desired that the basis of Mr. Cunynghame's calculation should be made public, so that the materials should exist for the formation of a sound judgment thereon.

As regards the cost of building, all depends of course on the kind of building proposed; but it would be melancholy, indeed, if an institution directly designed to elevate the ideas and refine the taste of the population of dismal and ugly South London, were to be housed in a building "of the plainest and most utilitarian character"—to say nothing of the quality of materials used in its construction.

But from an educational point of view an even more important consideration is the necessary amount of endowment. The allowance of 15*s*. a head, "including repairs and maintenance," seems very meagre, if fees are to be low, and at the same time first-class teaching power and management are to be secured, *and paid for*. To base an estimate on the current expenses of the Regent Street Polytechnic is to run the risk of serious error, for it is well-known that much of the work of organization and direction has there been performed gratis, or at far below market value, thanks to the enthusiasm of a few devoted workers. Can the Committees of the new Institutes call into existence a similar amount of enthusiasm among men of leisure and means in connection with each of the proposed Institutes (not, be it remembered, of a religious character), which will justify them in relying on being permanently saved the bulk of the expenses of management? If not, it is clear that a good deal will have to be added to the estimate of 15*s*. a head.

Another matter which is of importance from a financial point of view is the question of the position to be occupied by the day-school with respect to other sections of the new Institute. On this point, the language of the Commissioners' scheme is vague almost to the point of unintelligibility. There are evident advantages in utilizing the Polytechnic buildings in the day-time for the purpose of a school which may afterwards serve as a feeder to the evening classes. But it should be an organic part of the Institute; not a mere appendage, the existence of which may be tolerated so long as it interferes with no other department of work and claims no share in the endowment. Yet such seems to be the present intention of the Charity Commission, so far as we can gather from their published statements. The language of Mr. Plumbe's Report confirms this conclusion, against which it is time to record an emphatic protest. In our opinion, the day-school, if properly conducted, should ultimately become the corner-stone of the whole educational work of the Institute, for much more systematic teaching can be done in the case of boys working all their time than can be hoped for with students devoting a couple of evenings a week to instruction and recreation. Doubtless, in Regent Street a secondary school can be made self-supporting, and even profitable, by its fees; but such an attempt would be undesirable, and indeed impossible, in the case of a school for the "poorer classes" in a poor district. A high-fee'd school might perhaps fill itself at the expense of emptying other schools in the neighbourhood, but it would not fill the gap which wants filling. Under these circumstances, to condemn the day-school to pay its way is to condemn it to become a mere grant-earning machine, neglecting all subjects which do not pay, and constructing its curriculum strictly on the lines of the South Kensington Directory. What is wanted is a good modern school with a low fee, and a large number of scholarships for competition among the scholars of elementary schools. But such a school cannot be made self-supporting, and the Battersea Committee would do well to induce the Charity Commissioners, before it is too late, to recognize this fact frankly in the scheme which they are about to draw.

Again, we should be glad to know how wide a margin Mr. Cunynghame's estimate allows for the cost of what we may term "local adaptation." For example, in Mr. Plumbe's list of local industries we find chemical works, match factories, and gas-works. From this it would seem that there is room for the teaching of chemistry in its application to various industries. But such instruction, though it is one of the chief objects with which the technical side of the Institute is started, must involve extra cost, for it will not produce grant; and Mr. Plumbe's conclusion from his inquiry, that the "science and art

classes should be carried on so that the Government grant be earned," is a *non sequitur*; at all events until the Science and Art Department award grants for distinctively technical subjects under the new Technical Instruction Act.

We cannot help thinking that if due weight is allowed to these considerations the estimate of 15*s*. a head will be largely raised (unless compensation be sought by cutting down some of the more expensive trade classes); and as we suppose the endowment cannot be much increased, the number of students to be provided for must be necessarily diminished. In fact, the whole scale on which Mr. Plumbe has calculated the requirements of the Institute may have to be somewhat revised. To those who consider large numbers all-important, this may seem deplorable, but we are convinced that the Committee of the South London Polytechnic will prefer the interests of efficiency to those of temporary display.

One other matter which we notice with some surprise and regret is the apparent omission in the plans to provide committee-rooms and other accommodation which can be utilized by local working men's organizations. We referred in our former article to the importance of making the Institutes real working-class centres, and the reply of the Charity Commissioners to the deputation from the London Trades Council on the subject was supposed to be favourable to the provision in connection with each Institute of rooms which could be utilized on moderate payment by various working-class societies which now too often have to meet in public-houses. The omission of any such provision in the plans for Battersea is a serious blemish on the scheme, which, however, can easily be corrected, as soon as pointed out.

The Committee will have a great opportunity, which it is to be hoped they will use aright, of providing the inhabitants of South London with a technical and recreative Institute, which in its close adaptation to local needs may serve as model for all such Institutes in the future.

A GEOLOGICAL MAP OF THE ALPINE CHAIN.

Geologische Übersichtskarte der Alpen. Entworfen von Dr. Franz Noë. Mit einem Begleitworte. (Wien: Ed. Hölzel, 1890.)

GOOD, and in some cases even elaborate, geological maps exist for parts of the Alps; but one to exhibit the chain as a whole, without being on a scale so large as to be unwieldy or so small as to be indistinct, has been hitherto a desideratum. This has now been supplied by Dr. Noë. The scale adopted is 1 in 1,000,000, or about 16 miles to the inch, which very well satisfies both the above conditions. A glance at the list of authorities which have been consulted indicates that Dr. Noë has had no easy task; for in Alpine geology there are indeed consellors enough, but their multitude is not strength, for they are so often at variance.

At the present stage of knowledge, the chartographer must be content, in dealing with the crystalline schists (using that term in a rather wide sense), to colour his map petrographically—that is to say, he must, as far as possible, record facts and avoid theories. Dr. Noë has endeavoured, though not with complete success, to render his maps petrographical in the parts where doubt might arise, viz., those occupied by that crystalline series which, whatever may be its age, in the Alps always underlies any sedimentary rock to which a date can be assigned. The principle of coloration agrees very nearly with that suggested by the International Geological Congress at Bologna. Crimson denotes the deep-seated igneous rocks of the more acid type, dull green the more basic; two slightly different shades of red represent respectively the older (and in most cases more acid) volcanics and the newer volcanics. Four colours are employed to express the "crystalline schist" series: one, for the Central gneiss and some of the oldest mica-schists; another, for the less coarsely crystalline (and probably newer) mica-schists, together with calc-schists, chlorite-schists, &c.; a third, for certain crystalline schists, phyllites, and clay-slates of uncertain geological age; and marbles are indicated by a deep blue. Palæozoic rocks (exclusive of Permian) are coloured purple, the different series being distinguished by symbols; pale brown denotes Permian; tints of blue represent the Triassic and Jurassic strata; green signifies Neocomian and Cretaceous; orange the older Tertiary, flysch having a separate tint; one shade of yellow is used for Miocene and Pliocene; another for Diluvial and Alluvial deposits—the former a word of misleading origin, which ought to have long since disappeared from geological nomenclature.

Very wisely, Dr. Noë has included in his map something more than the Alps. Not only do we find the Jura, but also this region is extended far enough in the direction of Dole to exhibit the remarkable exposure of the old crystalline floor, north of that town. On the right bank of the Rhine, in the neighbourhood, of Sackingen, a considerable strip of crystalline rock is shown, the end of the great Schwarzwald *massif*; and north of the Eastern Alps we find the crystalline rocks indicated as they uprise from beneath the Miocene on the left bank of the Danube, as, for example, near Linz, and again at Pressburg. The geological colours also are carried down the east coast of the Adriatic as far as Spalato, so that the connection of the Istrian and Dalmatian Alps with the main chain is made perfectly clear. Unfortunately, however, Dr. Noë has not applied the same treatment to the Apennines, though their connection with the Alpine chain cannot be of less geological importance, for he brings the colours to an abrupt end a few miles west of Savona.

In one or two respects the above system of coloration seems open to criticism. The tint and the lines used to indicate mountain land are productive of some confusion, and increase the difficulty of identifying the colours, without, as we think, producing a compensating advantage. The use of three colours for the Trias-Rhætic seems a disproportionate subdivision when only one is allotted to Neocomian-Cretaceous. We are, however, disposed to differ more seriously—though only occasionally—from Dr. Noë as to his use of the colours for the divisions of the crystalline schists. One of these is made too inclusive, because it is applied to clay-slates and phyllites as well as to rocks which must be admitted to be crystalline schists. Granted that there is sometimes a difficulty in separating these in the field, we fail to see the propriety of deliberately effacing the distinction. Fortunately, however, this confusion, owing to the scale of the map, does not

seriously mislead the student, but we are more perplexed to discover the reasons which have led in some cases to the separation of the crystalline members of this group from certain of those in the other, and presumably older group, which is defined as consisting of "mica-schists calc-mica-schists, chlorite-schist, &c. To the latter are referred the schists—calcareous, micaceous, and chloritic —near Windisch-Matrei; to the former the great belts north and south of the Tauern range, which, for instance, occur respectively near Mittersill and Lienz. We cannot understand on what grounds these are distinguished. Further, the great group of schists which sweeps along on the eastern flank of the watershed of the Franco-Italian Alps, as, for example, near the Mont Genèvre, has the same colour as those of Windisch-Matrei; but petrographically they appear to us inseparable from the other group. By some geologists, as is well known, the "lustrous schists" have even been mapped (erroneously no doubt) as altered Trias.

Still, though we venture to dissent occasionally from Dr. Noë, and think that in all probability a wider personal knowledge of the Alps would have led him occasionally to modify a conclusion and to avoid some slight inconsistencies, we cannot conclude this notice without expressing our sense of the very great value of his work. He has placed a really good general map of the Alps within the reach of all students, for the price at which it is sold is surprisingly low. The map is accompanied by a useful descriptive pamphlet, to which Prof. Suess has written a short preface.

T. G. BONNEY.

OLD AGE.

Old Age. By George Murray Humphry, M.D., F.R.S, (Cambridge: Macmillan and Bowes, 1889.)

IN spite of pessimistic philosophies, man still regards life as worth living, and trusts to attain to a good old age, however miserable his life may seem to impartial critics. This desire, of course, is a necessary condition of human existence, and the destruction of it would entail the extinction of the human race—a contingency, however, which is never likely to arise. Hence, we have no doubt that this volume will be eagerly scanned by innocent persons who are still in hopes of finding some panacea which will enable them to attain the desired length of days.

But, alas, the number of their somatic cell generations is already fore-ordained in the germ from which they were developed; and no rule of life can increase this. No man by taking much thought can add a cubit to his stature, nor a decade to the predestined span of his existence. Yet the facts gathered together in this book may afford some hints as to the best way of attaining just this limit.

On p. 135, *et seq.*, Prof. Humphry reviews the chief characteristics in the mode of life of the favoured subjects of the work. He begins by saying that the results of the collective investigation respecting old age, "have not been such as to evolve anything very novel or startling, or to give rise to any fresh theories with regard to longevity and the means of attaining it," but only to "show that the maxims and laws which common-sense would dictate hold good, that the real *elixir vitæ* is to be found in the observance of them, and that, as a general rule, those persons live the longest who might be expected to do so."

The author also emphasizes the fact of the all-importance of inherited predisposition among the factors that tend towards producing longevity, and shows that nearly all the subjects of the return's came of a long-lived stock. In most of them, too, the body was well-proportioned and developed, brain development fair, and there was a remarkable absence of degenerative changes in the arteries and cartilages. According to the author, their essential characteristic is that all parts of the body are so well balanced, that the senile decay of function goes on in them all simultaneously, and at an equal rate, so that, *e.g.*, the vascular system is not overloaded and overworked by a too vigorous digestive apparatus, nor the vessels worn out by an over-excitable nervous and cardiac mechanism, so that if we could induce all our organs

> "to arrange
> This not to be avoided change,
> So as to change together,"

we should have gone far towards attaining the secret of long life.

Most of the persons described were temperate, taking little alcohol and meat, and lived active open-air lives. There are one or two startling exceptions to the former rule, however; such as the centenarian who "drank like a fish all his life," and several others who had always indulged pretty freely in stimulants.

Another point that Prof. Humphry lays stress on is the fact that most of these people were early risers, and could do with little sleep. It seems that the anabolic processes are more complete and regular when they are accomplished quickly. *Apropos* of this, he quotes with approval the dictum of the Duke of Wellington: "When one turns in bed, it is time to turn out."

In discussing the general aspects of his subject, he shows that old age may be said to be a product of civilization, the law of the "weakest to the wall" being altered by the growth of sympathy, and of love for others. But the continued existence of old people among communities may (partly, at all events) be accounted for on more utilitarian principles. Weismann remarks:—

> "It [old age] is obviously of use to man, for it enables the old to care for their children, and is also advantageous in enabling the older individuals to participate in human affairs, and to exercise an influence upon the advancement of intellectual powers, and thus to influence indirectly the maintenance of the race."

Thus we see the production of old age could be accounted for simply on the laws of natural selection among nations.

The fertility of these long-lived individuals is also above the normal (the average of children born to each, whether man or woman, being six), and many of them seem to have borne or begotten children to an advanced age. This, again, is in accordance with the view advocated by the biologist just quoted—viz. that a lengthening of life is connected with the increase in the duration of

reproduction. The effects of this fertility of long-lived people must give their stock an advantage in the race for existence, so that one would expect their number, in proportion to the rest of the population, gradually to increase.

The last chapter gives a short account of the maladies of old people, and is chiefly of medical interest.

Besides the general account of the subject, Prof. Humphry gives all the analyses of the British Medical Association returns, which furnish the material for the book. There are several good photographic illustrations: the frontispiece, portraits of a man and his wife (both over 101 years), and others, representing sections through the neck of the thigh-bone, and the jaw of old people. With regard to the femur, Prof. Humphry points out that there is no foundation for the generally accepted idea that the head in old people sinks to or below the level of the great trochanter, and the illustration certainly bears out his criticism.

Perhaps the happiest feature of the book is its optimism. "It is satisfactory to note how many of the very aged are in good possession of their mental faculties —taking a keen interest in passing events, forming a clear judgment upon passing events, and full of thoughts for the present and future welfare of others."

An old age like this is worth striving to attain, although one may never be free from the dread of dying "from the head downwards," and so lingering on in

> "Second childishness and mere oblivion,
> Sans teeth, sans eyes, sans taste, sans everything."

E. H. S.

THE ELEMENTS OF ASTRONOMY.

The Elements of Astronomy. By Prof. C. A. Young, Ph.D., LL.D. (Boston and London: Ginn and Co. 1890.)

THIS is a valuable addition to the existing text-books of astronomy for the use of those who intend to study the subject seriously. It has much in common with the same author's larger work on "General Astronomy" (see NATURE, vol. xxxix. p. 386), but we are assured that it is not merely an abridgment, but has been worked over with special reference to a high-school course. It is assumed that the students have mastered the ordinary elementary subjects, and are acquainted with elementary algebra and geometry.

The book covers quite as much ground as can be expected for an elementary course, although many of the subjects are merely glanced at. Practically everything, with the exception of the more difficult problems of mathematical astronomy, is considered more or less. The opening chapters deal with definitions, the geometry of the sphere, and the determination of latitude and longitude. Chapters on the earth's dimensions and motions, the moon, sun, planets, comets, stars, and nebulæ, then follow. An appendix includes topics which might be considered beyond an elementary book, but are still of sufficient importance to form part of a high-school course.

Astronomical physics receives a fair share of attention, but here the book is necessarily more open to criticism than in the parts dealing with well-established facts and principles. There are few general text-books which treat this important branch of astronomy in a satisfactory manner, and it is perhaps not to be wondered at, as the constantly increasing number of new observations necessitate considerable changes in our ideas. As far as a consideration of the facts is concerned, however, Prof. Young has done his work admirably, but this cannot be said of his treatment of the various conclusions which have been drawn from them. In his introduction, Prof. Young tells us that he has tried to treat every subject in such a way as "to discourage narrow and one-sided ways of looking at things, and to awaken a desire for further acquisition." However he may succeed with his readers, it does not seem that he has altogether taken this lesson to heart himself, for we find him dismissing suggestions without a complete hearing. For instance, in connection with the theory that sun-spots are formed by the downrush of cool materials into the photosphere (p. 130), he states that it is not easy to reconcile this view with the distribution of the spots over the sun's surface. Further enquiry on his part, however, would have shown him that the theory in its extended form suggests that the spot-forming material is mainly formed of vapours which have condensed in the cool outer layers of the sun's atmosphere (in the same way as water-vapour condenses in our own), and also gives an explanation of the way in which the material may be localized over the spot-zones. The author is notably cautious with regard to new things, but we are surprised to find that he continues to adopt Secchi's classification of star spectra (p. 317), seeing that it does not satisfactorily treat bright-line stars like γ Cassiopeiæ, and those of Orion which give almost continuous spectra. The classifications suggested by Vogel and Lockyer both have the advantage of detail, and the latter is certainly the most philosophical. On p. 318 it is stated that stars of Secchi's fourth type usually "show a few bright lines," in addition to the carbon absorption bands, an idea of Secchi's which was shown to be erroneous several years ago.

The book is abundantly illustrated, and most of the diagrams are excellent. Fig. 119, however, gives a very bad impression of the spectrum of a nebula, the three bright green lines being represented as almost equidistant, whereas they practically form a triplet. A useful "Uranography" is given at the end. This embraces the more important celestial objects in the northern hemisphere and some degrees south, and is accompanied by a series of star maps. In the maps a convenient system of indicating magnitudes is adopted, but it has the disadvantage of destroying the appearances of the constellations for rapid identification.

A. F.

OUR BOOK SHELF.

Physiology of Bodily Exercise. By Fernand Lagrange, M.D. (London: Kegan Paul, Trench, and Co., 1889.)

THIS book at first sight reminds one of the saying that a German takes a year to make a research, and a week to write an account of it, while a Frenchman takes a year to write a book on one week's work. The only original part consists of a few experiments on the influence of fatigue in producing increased excretion of urates in the urine. The author ascribes most of the ill effects of

fatigue to the presence of uric acid in the blood—in fact, considers a fatigued man to be in exactly the same condition as a gouty man. His observations, however, seem to have been very few in number, and the analyses were all made for him by a friendly chemist. Still, it is unfair to the book to regard it as a contribution to the advance of physiological science. It is really an excellent little account of the physiology of bodily exercise, and its *rôle* in the maintenance of health, by a medical practitioner. It seems to be chiefly culled from the standard French works on general physiology, and on the physiology of movement. The author has digested his materials well, and so produced a very readable and lucid account of his subject. For a book of its class, it is remarkably free from mistakes, though physiologists might not agree with him in his account of the production of breathlessness or the causation of gout.

The style is simple, and the book is well adapted for popular use, and ought to find favour with our exercise-loving countrymen. E. H. S.

Boilers—Marine and Land. By Thomas W. Traill, F.E.R.N., M.Inst.C.E. Second Edition. (London: Charles Griffin and Co., 1890.)

THIS volume is a second edition of a work noticed in these columns last year. It was then a pleasure to express the opinion that the work would be useful to all connected with this particular branch of mechanical engineering. The author has found it necessary to extend the tables of scantlings, &c., from 160 to 200 pounds pressure per square inch. This in itself is sufficient evidence of the continued increase of steam pressures used in marine and stationary engines—probably the only practicable direction in which greater economy of fuel is to be obtained. These increased steam pressures have also the advantage of diminishing the gross weight of machinery on board ship.

The greater use made of mild steel by engineers generally is interesting, considering the fight the steel manufacturers had a few years ago to get it used at all in place of iron for many purposes. Mr. Traill observes that, "notwithstanding the peculiarities of mild steel, it is a material which may be used with safety and advantage, if proper precautions be taken and due consideration given to these peculiarities; possibly it has fewer infirmities than iron; and there can be no doubt that it is a better and more serviceable material for general use in the construction of boilers." This is the experience of most engineers intimate with the general behaviour of the material when being worked up into boilers and other constructions. To the many tests and safeguards specified to prevent the use of a brittle and bad steel in any erection is due the present excellence of this material, nor should they now be in any way relaxed, for to accept material, either iron or steel, on any particular brand is a mistake.

The general utility of the work has been increased by the addition of other matter and tables. The volume cannot fail to be of very great use to engineers. It is nicely printed, got up in a handy size, and strongly yet pliably bound. N. J. L.

The History and Pathology of Vaccination. Edited by Edgar M. Crookshank, M.B. Two Vols. (London: H. K. Lewis, 1889.)

THE arguments adopted in this work belong to a mental attitude identical with that displayed by anti-vaccinators in their clamorous treatment of the subject. They are sophistical from beginning to end, and even as a book of reference the volumes are not without drawbacks.

Firstly, the argument is that cow-pox is to be regarded as akin to syphilis rather than to small-pox, and that therefore cow-pox is no protection against small-pox. On this hypothesis ulcerated arms sometimes occurring after vaccination are to be regarded as reversions to type, rather than as due to the ill-treatment by over-anxious mothers not content to let Nature alone in her progress towards recovery. Having assumed that vaccination is no protection against small-pox, the book goes on to show that the only means we have of controlling the devastations of this disease is by attention to sanitary arrangements and by isolation, perhaps combined with judicious inoculation. The latter, the book assures us, is a more scientific procedure than the inoculation of cow-pox. Next, the author is very angry with Jenner for calling vaccinia, "cow-pox" or "variola vaccinia." To this stroke of dexterity by Jenner is to be attributed, says Prof. Crookshank, all the credit that vaccination has attained; thus for a single happy thought Parliament gave Jenner £30,000 as a consequence of his conceit, and England has been made to submit to the most tyrannical of laws.

This carping at the pioneer of new knowledge, and more especially at those forecasts of his which necessarily could only be verified by the lapse of time, is certainly not calculated to shake the faith of those who now fully comprehend not only the immense value of vaccination, but also the small amount of mischief which it has ever done.

The best that can be said for Prof. Crookshank's work is that it is well published. The printing is bold and clear, and the lithographs, such as they are, well reproduced.

Vol. ii. contains reproductions of original papers, most if not all of which are out of print, and cannot now be obtained except at fancy prices.

Had Prof. Crookshank been satisfied with editing these, and had he refrained from expressing his opinions, we should have been grateful to him. The book does not pretend to be a practical work on the subject of which it treats; and for the rest it might have been compiled by the average anti-vaccinator. ROBERT CORY.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Transmission of Acquired Characters, and Panmixia.

I SUPPOSE that a correspondent has no claim to limit the scope of a discussion in such a journal as NATURE. At the same time I feel it to be a rather severe burden when I am called upon to expound, in answer to one letter after another, the merest common-places of the subject under discussion, and to retail in this place the substance of books like Weismann's "Essays" and Wallace's "Darwinism" (to which the attention of your readers has been already drawn by reviews), not to mention the "Philosophie Zoologique" and the "Origin of Species." It seems to me that there might be interest and profit in opening your columns to the statement of newly observed cases which seem to tell in favour of either the Lamarckian or the anti-Lamarckian theories, or to novel criticisms of any cases which have already been discussed elsewhere; but surely the repeated citation of familiar exploded "cases," and the reiteration of arguments and beliefs which have long since received attention, is not fair to the writers who have dealt with these cases and these arguments in admirable treatises which are well known (I am happy to think) to nearly all serious students of these questions.

When I saw the distinguished name of Mr. Herbert Spencer at the end of a letter in your issue of March 6, I anticipated some real contribution to the discussion as to whether acquired characters are transmitted or not. Mr. Spencer some few years ago expounded his convictions in favour of Lamarck in one of the monthly reviews. His present letter is not only disappointing, but is unfortunately likely to mislead the uninformed. Mr. Spencer states what we all know, viz. that Mr. Darwin considered that the effects of habit and of use and

disuse are transmitted from the affected generation to its offspring. He refers by chapter and page to the instances which Mr. Darwin considered as examples of the transmission of the effects of habit or of use and disuse. He then says: "Clearly the first thing to be done by those who deny the inheritance of acquired characters is to show that the evidence Mr. Darwin has furnished by these numerous instances is all worthless." I entirely disagree with this way of putting the matter. It is not necessary to show that anything Mr. Darwin wrote was "worthless," but it is necessary to show that certain facts cited by Mr. Darwin admit of another interpretation or explanation than that which he gave to them. Naturally those who have taken up the anti-Lamarckian position have done long ago what Mr. Herbert Spencer says is the first thing for them to do. Of course the cases cited by Darwin were the first to be dealt with. It is extremely unfortunate that Mr. Spencer has not come across the work in which this is done. Otherwise, instead of a well-meant direction from Mr. Spencer as to what we ought to do, we might have the advantage of reading what he has to say after considering what has been done. It is seven years since Prof. Weismann published his essay on heredity; last spring this and other essays appeared in English under the auspices of the Clarendon Press. In that particular essay Darwin's cases are dealt with at length. Am I to reproduce Prof. Weismann's essay or a *précis* of it in this letter? Will not Mr. Spencer and others who are interested in these matters read Weismann's "Essays"? I think that those who will take the trouble to do so will see that Mr. Spencer's injunction was superfluous.

It is, however, apart from other branches of the question, important that a correct appreciation of Mr. Darwin's position in this matter of the "transmission of acquired characters" should be arrived at. Mr. Herbert Spencer's letter is, I think, likely to produce an erroneous conception on this matter. We know from his letters published since his death that Darwin held the "Philosophie Zoologique" to be "veritable rubbish"—"extremely poor; I got not a fact nor an idea from it." The notion that his own view was a modification of Lamarck's appeared to Darwin absurd. The "obvious view" was propounded by Lamarck, he says, "that if species were not created separately they must have descended from other species, and I can see nothing else in common between the 'Origin' and Lamarck." This was Mr. Darwin's attitude of mind to Lamarck's theory, and the cases in which he attributes importance to the effects of use and of disuse, and to acquired habit, and consequently to the Lamarckian principle of the transmission of acquired characters, are clearly to be regarded as concessions or admissions on his part, given with increasing generosity in the later editions of the "Origin"; but always treated as of quite subordinate importance. It is not going too far to say that Mr. Darwin never troubled himself very much with the question as to whether acquired characters are transmitted or not. It was the object of his works to show that the main effective principle in the origin of species is the natural selection in the struggle for existence of congenital characters. He explicitly states that he believes other causes to be at work; one of which at least, viz. sexual selection, he himself investigated at length. It must be remembered that no evolutionist in Darwin's life-time had prominently challenged the truth of the Lamarckian assumption that acquired characters are transmitted. For Darwin it was sufficient to show that, granting such a process to take place, it would not account for much; he was content to accept it as a subordinate factor. His view is best stated in his own words in the "Origin of Species": "On the whole we may conclude that habit, or use and disuse, have, in some cases, played a considerable part in the modification of the constitution and structure."

Whilst it is true that Mr. Darwin in various parts of his works alludes to cases which he interprets as due to the transmission of characters acquired by parents through habit, use, or disuse, it is obvious, when we read what he has to say in each case (as in the examples cited by Mr. Herbert Spencer), that he preferred, where it occurred to him another interpretation. Thus, after referring to the wings of the logger-headed duck and the domestic Aylesbury duck as dwindled by the transmission in successive generations of the effects of disuse, he interposes his own explanation by natural selection of the wingless beetles of Madeira, prefaced by the words: "In some cases we might easily put down to disuse modifications of structure which are wholly or mainly due to natural selection." He refuses to regard the defective anterior tarsi of dung-beetles as due to inherited mutilation, though he supposes they may have become deficient through disuse. He regards the defective eyes of cave-animals as due to the inheritance of the effects of disuse. I can scarcely doubt that, had it occurred to him, he would have preferred an explanation similar to that given by him of the wingless island beetles, viz. that a natural selection of animals with defective eyes takes place in a cave; since ultimately only those remain in a cave and breed in it which, in the course of their wanderings, are unable to see the faint light which penetrates to a great distance from the mouth, and must guide all those but the congenitally blind or weak-sighted to the exterior. The defective eyes of moles are ascribed by him not merely to disuse but to the selective action of inflammation. The case of the silkworm caterpillars with defective instincts (which is one of those given by Mr. Spencer) does not appear to me to bear on the present question. Of acquired characters, other than those due to disuse, Mr. Darwin accepts very few as being transmitted. He accepts the statements of Brown-Séquard as to the transmission of the effects of mutilations of guinea-pigs only so far as to "make us cautious in denying such transmission." He regards the dislocation of the eye of flat-fishes as due to the inheritance in successive generations of an increasing displacement caused by muscular effort. Besides these two instances (noted by Mr. Spencer) there is one other prominent passage in which Darwin asserts his belief in the inheritance of an acquired character which is not merely the result of disuse. I am anxious to separate those cases which Darwin speaks of as "due to the effects of disuse," for a reason which will appear below. The additional passage not noted by Mr. Spencer is this ("Origin of Species," p. 206, sixth edition):—"If we suppose any habitual action to become inherited—and it can be shown that this does sometimes happen—then the resemblance between what originally was a habit and an instinct becomes so close as not to be distinguished. If Mozart, instead of playing the pianoforte at three years' old with wonderfully little practice, had played a tune with no practice at all, he might be truly said to have done so instinctively. But it would be a serious error to suppose that the greater number of instincts have been acquired by habit in one generation and then transmitted by inheritance to succeeding generations. It can be clearly shown that the most wonderful instincts with which we are acquainted—namely, those of the hive bee and of many ants—could not possibly have been acquired by habit."

The cases of the epileptic guinea-pigs, the eyes of flat-fishes, and of some acquired habits, have been discussed by Weismann and by Wallace. I will not now allude further to those classes of cases. But I am anxious to draw attention to the special subject of the "effects of disuse" as set forth by Mr. Darwin. This phrase is not only used by him in regard to special instances, but, in treating of the large subject of rudimentary organs, he frequently refers to the "effects of disuse." He says, "It appears probable that disuse has been the main agent in rendering organs rudimentary" ("Origin," p. 401).

Now I am anxious to point out three things in regard to the 'effects of disuse." (1) There are other possible effects of *disuse* of an organ than the dwindling of that organ in one generation, and the inheritance of the organ in a diminished size by the next generation. (2) The anti-Lamarckians attribute a very great effect to disuse, although they do not attribute to it the particular result which Lamarck did. (3) The particular way in which, according to the anti-Lamarckians, disuse acts so as to lead to the dwindling or complete loss of the disused organ has been called by Weismann by a convenient name—"panmixia." The doctrine of panmixia is already indicated by Darwin himself, and in view of this fact we must suppose that, when he attributed the loss or dwindling of an organ to "disuse" or the "effects of disuse," he did not necessarily (though probably he frequently did) refer to the Lamarckian *modus operandi* of disuse, but may very well have had in mind the results which are attributed to disuse by the anti-Lamarckian doctrine of panmixia.

The doctrine of panmixia is this. When there is no longer, owing to changed conditions of life, any use for an organ, it will cease to be the subject of natural selection. Consequently all possible variations of the organ will have (so far as the now lapsed use of the organ is concerned) an equal chance. Amongst the possible variations there will be the variation in the direction of increased size, and its exact complement—the variation in the direction of diminished size. Prof. Weismann has stated briefly that this equal survival of all possible variations must lead to the

dwindling and ultimate loss of the organ. I would, however, venture to supplement what he has said by the following: viz., given the state of panmixia, it is apparent that variations in the direction of excessive size will be injurious—both as taxing the nutriment of the organism, and often as mechanical encumbrance. On the other hand, variations in the direction of greatly diminished size will be advantageous, as causing a diminished tax on the resources of the organism. Now it is a demonstrable fact that excessive variations in both directions *do* naturally though rarely occur—probably more often than is supposed, since we do not see all the young born. If the variations in the direction of excessive diminution of a useless organ (as, for instance, tailless cats or hornless sheep) survive as being less taxed—whilst the complementary variations in the direction of excessive size tend in the struggle to die without reproducing, owing to their awkwardness and their relatively greater burden in life—then it is clear that panmixia may lead rapidly to the dwindling and eventual extinction of a disused organ without any transmission of *acquired* parental character. The fact that there is no use for an organ—or, in other words, the "effect of disuse"—is that the congenitally small varieties of the organ survive, and are even favoured in the struggle for existence.

Whilst Weismann has the merit of having insisted on a form of his doctrine as the effective reply to those who argue in favour of Lamarck's theory of the transmission of acquired qualities from instances of "disuse," it is yet the fact that Mr. Darwin himself recognized and formulated the doctrine of panmixia in the last (sixth) edition of the "Origin of Species," published in 1872; and he even went further than Weismann, for he associated the principle of the economy of material with the principle of the cessation of selection. It is therefore, it seems to me, not at all improbable that when Darwin refers, here and there throughout his works, to a reduced or rudimentary condition of an organ as "due to disuse," or "explained by the effects of disuse," he does not *necessarily* mean such effects as the Lamarckian second law asserted and assumed (though often he does appear to mean such); but he may mean, and probably had in his mind, the effects of disuse as worked out through panmixia and economy of growth.

The passages in Darwin which seem to me to have been missed or neglected by those who think panmixia altogether a new idea are as follows:—

(1) "If under changed conditions of life a structure before useful, becomes less useful, its diminution will be favoured for it will profit the individual not to have its nutriment wasted in building up a useless structure." After an example in point from the group of the Cirripedia, Darwin continues: "Thus, as I believe, natural selection will tend in the long run to reduce any part of the organization as soon as it becomes, through changed habits, superfluous, without by any means causing some other part to be largely developed in a corresponding degree" ("Origin of Species," sixth edition, p. 118).

(2) "Organs, originally formed by the aid of natural selection, when rendered useless, may well be variable, for their variations can no longer be checked by natural selection. . . . It is scarcely possible that disuse can go on producing any further effect after the organ has once been rendered functionless. Some additional explanation is here requisite, which I cannot give. If, for instance, it could be proved that every part of the organization tends to vary in a greater degree towards diminution than towards augmentation of size, then we should be able to understand how an organ which has become useless would be rendered, independently of the effects of disuse, rudimentary, and would at last be wholly suppressed; for the variations towards diminished size would no longer be checked by natural selection. The principle of the economy of growth explained in a former chapter [cited in quotation No. 1], by which the materials forming any part, if not useful to the possessor, are saved as far as possible, will perhaps come into play in rendering a useless part rudimentary" ("Origin of Species," sixth edition, pp. 401-402).

I had written thus far, and intended to finish this letter by asking if the anti-Lamarckians are not really carrying out the spirit of Darwin's doctrines, although not the absolute letter, when I received your issue of March 13, containing a long letter from Mr. George Romanes, headed "Panmixia." In that letter Mr. Romanes, whilst amending (as I have done above) Prof. Weismann's statement of the principle of panmixia, makes the definite assertion that "it is remarkably strange that this principle should have been overlooked by Mr. Darwin."

Probably your readers will be as much astonished as I was when they read the extracts I have above given from the "Origin of Species" by the side of Mr. Romanes's letter.

After dismissing Mr. Darwin, Mr. Romanes proceeds to say: "In this connection, however, it requires to be stated that the idea first of all occurred to myself, unfortunately just after the appearance of his last edition of the 'Origin of Species.'"

Now, inasmuch as the idea in question is (as I have shown above) formulated in the last edition of the "Origin of Species," I confess that I do not think it requires to be stated that the idea occurred to Mr. Romanes shortly after the publication of that work. What more natural? The idea occurred to me also shortly after the passages above quoted from Mr. Darwin were published. It certainly never appeared to me "unfortunate" that this was the case, and I cannot see where the misfortune comes in in regard to Mr. Romanes. As soon as the matter had taken root in his mind, Mr. Romanes published in NATURE, March 12, April 7, and July 2, 1874, an exposition of the importance of the principle of cessation of selection as a commentary upon a letter by Mr. Darwin himself (NATURE, vol. viii. pp. 432, 505) in which Mr. Darwin had suggested that, with organisms subjected to unfavourable conditions, all the parts would tend towards reduction. Mr. Darwin, with his usual kindly manner towards the suggestions of a young writer, gives at p. 309 of vol. ii. of "Animals and Plants under Domestication" (second edition), Mr. Romanes's view, "as far as it can be given in a few words." The view, as it there appears in Mr. Darwin's words, is certainly *not* the same as that which Mr. Romanes has expounded in NATURE of March 13, 1890 (p. 437), and since it represents what Mr. Darwin had been able to gather from Mr. Romanes's letters to NATURE of 1874, it is not at all surprising that Mr. Darwin did not recognize any resemblance between it and his own statement, viz. that "the materials forming any part, if not useful to the possessor, are saved as far as possible," thus "rendering a useless part rudimentary." Whether this is, or was, Mr. Romanes's view or not, it is Darwin's, and is the essence of the anti-Lamarckian view of the effects of disuse.

March 15. E. RAY LANKESTER.

Exact Thermometry.

SHORTLY after the publication of my second letter on this subject (NATURE, January 23, p. 271) I received a letter from M. Guillaume, who very kindly called my attention to a paper by Prof. J. M. Crafts (*Comptes rendus*, xci. p. 370), in which the "plastic theory" is discussed. Prof. Crafts states that he has subjected thermometers to prolonged heating at 355° C., under various conditions as regards pressure, the internal pressure being in many cases considerably greater than the external, but that there was invariably a rise of the zero-point. The experiments were carried out in very much the same manner as that described in my first letter (NATURE, December 19, 1889, p. 152), and had I known at the time of the earlier work of Prof. Crafts, I should of course have referred to it. Prof. Crafts also describes and quotes experiments with air-thermometers, the temperature in one determination by Regnault being as high as 511° C., and the internal greater than the external pressure; in every case the bulb diminished in volume. From these results, Prof. Crafts concludes that it is not proved that pressure plays any part in the contraction of the glass.

My experiments can therefore be regarded as little more than confirmatory of the earlier work of Prof. Crafts and others, but as such it may be worth while to give the results. The method adopted was fully described in my first letter, and it is therefore only necessary to repeat that in thermometer A the external pressure exceeded the internal, while in thermometer C there was considerable internal pressure, but no external. According to the plastic theory, therefore, the zero-point of A should have risen, while that of C should have fallen. The results previously described were regarded as insufficient by Prof. Mills, and I have therefore continued the heating for a much longer time.

I have also made similar experiments with two other thermometers belonging to the same batch, at a temperature of about 356°, the thermometers being heated in the vapour of boiling mercury. During the first three hours, the two thermometers *a* and *b* were treated in precisely the same manner, as regards pressure, as A and C, and it will be seen that the zero-point of *b* showed a slightly greater rise than that of *a*. Afterwards, air was admitted into thermometer *a*, so that there was an excess of internal over external pressure in both thermometers, but the excess was greater by one atmosphere in *b* than in *a*.

The results obtained are given in the followi[ng table:—]

Temperature 280°.

Total time in hours.	Duration of each heating.	Zero-point of A.	Rise of zero.	Zero-point of C.	Rise of zero.	Mean rise of zero per hour.
0	—	0°·15	—	–0°·1		
2	2	0·5	0·35	+0·3	0·4	0·187
7·5	5·5	1·3	0·8	1·1	0·8	0·145
12	4·5	2·0	0·7	1·8	0·7	0·156
17	5	2·3	0·3	2·05	0·25	0·055
22·5	5·5	2·6	0·3	2·15	0·1	0·036
29	6·5	2·95	0·35	2·5	0·35	0·054
35	6	3·15	0·2	2·8	0·3	0·042
86	51	4·1	0·95	3·95	1·15	0·021
133	47	4·8	0·7	4·9	0·95	0·018
201	68	5·25	0·45	5·5	0·6	0·008
369	168	6·5	1·25	6·8	1·3	0·008

Temperature 356°.

		a		b		
0	—	0°·4	—	0°·05		
3	3	6·0	5·6	6·1	6·05	1·942
6	3	8·0	2·0	8·1	2·0	0·667
12·5	6·5	10·3	2·3	10·35	2·25	0·350
15	2·5	10·95	0·65	11·1	0·75	0·280
66	51	16·1	5·15	16·1	5·0	0·100
113	47	18·45	2·35	18·3	2·2	0·048
181	68	20·1	1·65	20·0	1·7	0·025
205·5	24·5	20·75	0·65	20·6	0·6	0·025
221·5	16	20·9	0·15	20·7	0·1	0·008
292	70·5	21·8	0·9	21·7	1·0	0·013

The last result at 356° is a little uncertain, owing to a breakage of the apparatus.

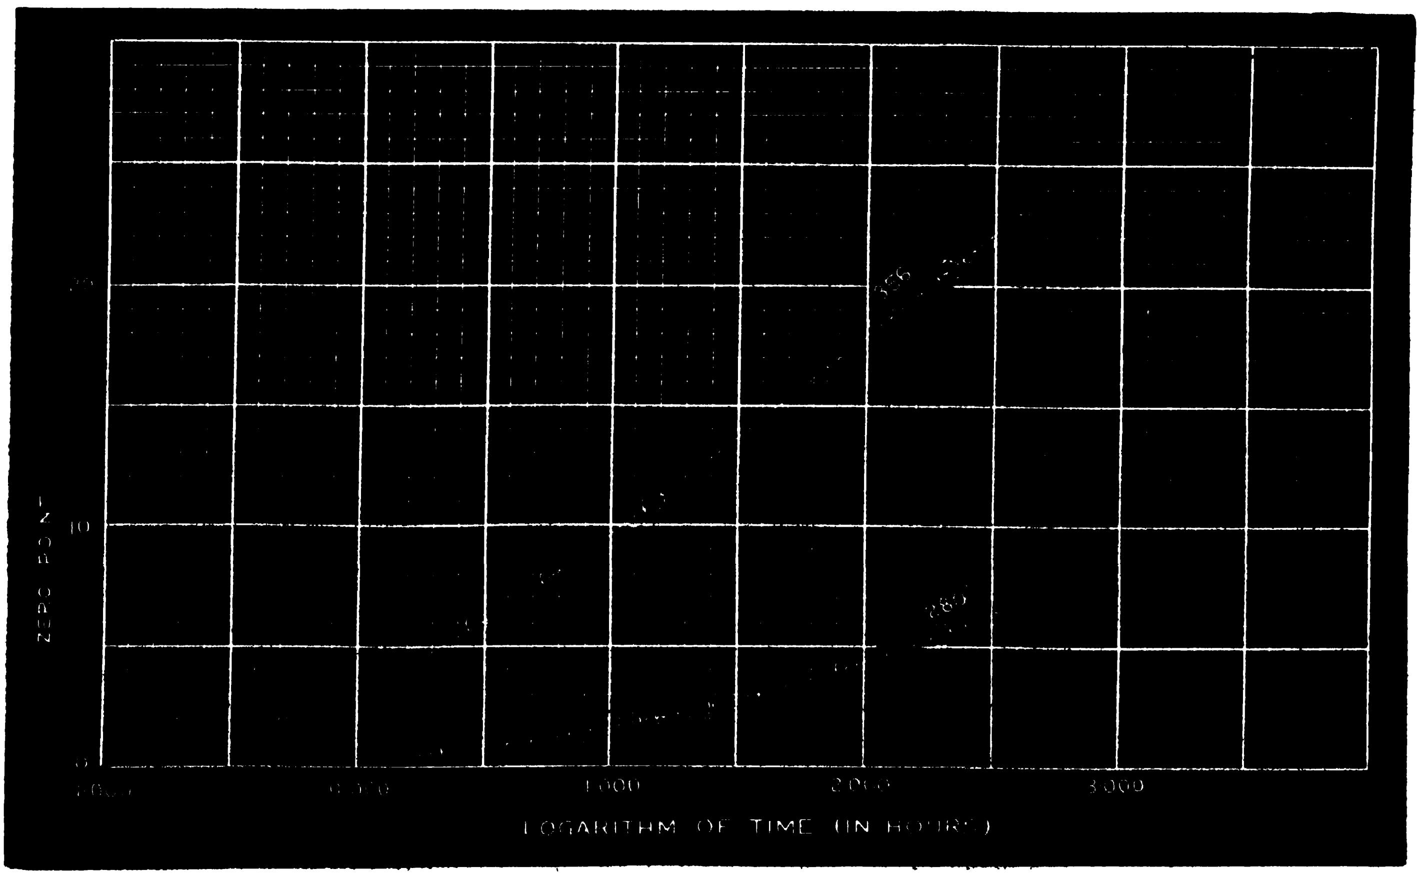
I may also mention that M. Guillaume has informed me that M. Tonnelot has heated several thermometers to 450°, and that, notwithstanding a considerable internal pressure, a rise of the zero-point was observed in every case.

All these results seem to lead unmistakably to the conclusion that pressure has little or no effect on the rise of the zero-point.

Three questions remain to be discussed—

(1) Would the total rise of the zero-point be different if two similar thermometers were subjected to sufficiently prolonged heating at different temperatures? At first sight, it would certainly appear that at 356° the total rise with my thermometers must be greater than at 280°, but I do not feel satisfied that the proof is sufficient. If we map the observations of zero-point against the time of heating, curves are obtained which appear as if they might become horizontal after a few weeks or, possibly, months; but if, instead of the actual times, we take their logarithms—as in the diagram—as abscissæ, there is no appearance of an approach to the final state at either temperature. But while at 356° the curve has become almost a straight line, at 280° there appears to be an increasing tendency towards the vertical direction. I do not for a moment argue that the curves indicate that the maximum rise would be the same at both temperatures if the experiments were carried on for a sufficiently long time; but, at the same time, I do not think that they afford any convincing proof that the total rise would be different. The results merely tend to increase my scepticism as to the value of the determination of the maximum rise at 0° obtained by extrapolation of the curve constructed from observations at that temperature. It does not appear to me that it would be justifiable to extrapolate these curves at all, and I am afraid that they do not throw much light on the total rise of zero-point at either temperature. Very much more prolonged heating would be necessary before arriving at a definite conclusion.

(2) With regard to the causes of the contraction of the bulb, I have no hesitation in admitting that—as shown by M. Guillaume—the removal of the condition of strain caused by the more rapid cooling of the *outer parts* of the glass, is insufficient to account for the results. No doubt we must also take into account the too rapid cooling of the glass *as a whole*, which prevents the molecules from assuming the position of greatest stability, perhaps in the same sort of way that the assumption by sulphur of the monoclinic or the more stable rhombic form depends on the rate at which solidification takes place. That there are other causes besides these two does not at present appear to me to be proved.



(3) Lastly, there is the question raised by Mr. Tomlinson, as to whether repeated heating and cooling between wide limits of temperature is more effective in raising the zero-point than prolonged heating at the higher temperature. The points representing the individual observations fall very fairly on the curves constructed from them, and do not seem to indicate any noticeable difference in the effect of long or short heating. The results can hardly, however, be regarded as decisive.

University College, Bristol, March 1 SYDNEY YOUNG.

Foreign Substances attached to Crabs.

SINCE *Hyas* is one of the most abundant Crustaceans found off the east coast of Scotland, Mr. Holt must adduce considerably more than two instances before it can be admitted that the attachment of Simple Ascidians to this crab is at all a usual occurrence. If it is, I should still be anxious to inquire whether the crab does not—in spite of the apparent difficulty of the operation—place the Ascidians upon its back with its own nippers. I may cite Gosse's well-known experiment with *Pagurus prideauxii* and *Adamsia palliata*, described in his "Year at the Shore," for the purpose of analogy. But Mr. Holt will find a case, probably quite similar to that which he mentions, in Bell's "Stalk-eyed Crustacea." Two specimens of *Hyas araneus* were found with oysters attached to their backs, that on the larger crab being three inches in length, and five or six years old, probably a much more "serious incubus" than Mr. Holt's Tunicates. The crab's carapace was but two and a quarter inches in length. Hence, despite the "world of weight upon its shoulders," Mr. Thompson concluded that "the presence of this oyster affords interesting evidence that the *Hyas* lived several years after attaining its full growth." Probably the larvæ of the oysters, and of the Ascidians also, happened to alight upon the crabs at the end of their free-swimming existence, although six or seven years seems to me to be a remarkably long age for a *Hyas*.

Barnacles upon the backs of *Maia*, *Carcinus*, &c., are also due to the same, as it were, accidental cause.

But, whatever the explanation, these exceptional cases do not alter the fact that the foreign bodies found upon *Hyas* are usually fixed there by the crab itself. The specimens I have seen have been covered with fragments—not living colonies—of Algæ, Hydroids and Polyzoa, which are fastened by the hairs of the crab's carapace and legs exactly as in *Stenorhynchus*, and in this crab the process of attachment has been frequently observed here and accurately recorded.

At the same time I by no means hold that the two groups which were defined in my previous letter are absolutely marked off from one another. The hermit crabs make use of both methods of protection. Bits of Sponges may frequently be seen upon the carapace of *Maia*, *Stenorhynchus*, and *Inachus*, and I have occasionally found colonies of *Leptoclinum* and *Didemnum* upon both *Maia* and *Inachus*. In these cases the inconspicuous appearance is not lost, but the attachment of small Sponges and Didemnids is probably an additional protection against the numerous night-feeding fishes, which hunt their prey by the senses of smell and touch.

As to the inedibility of *Tunicata*, I did not—as Mr. Holt states—"assume" it. I have experimentally found it to be a fact (as I stated in my letter) that the odour and taste of "*Tunicata*, and especially Compound *Tunicata*," are almost invariably sufficient to prevent fishes from eating them. Exceptions do not disprove the rule, and it is quite possible that *Pelonaia* is not distasteful. But this is not established by a few specimens having been taken on one or two occasions from the stomachs of Cod, Haddock, and Dab; and although Mr. Holt quotes Prof. McIntosh as speaking of the "abundant" occurrence of *Molgula arenosa* in the stomachs of Cod and Haddock, he will find upon reading Prof. McIntosh's words again, that they are open to a different interpretation.

In my previous letter I omitted to mention that a species of hermit crab also, *Eupagurus lucasii*, takes advantage (regularly?) of the distastefulness of Compound Ascidians. Mr. Harmer has, with much kindness, examined for me a specimen in the Cambridge Museum. The crab inhabits a univalve which is covered with *Distaplia magnilarva*.

Mr. Holt's statement that "*Actinia mesembryanthemum* is certainly a favourite food of the Cod" is so astonishing that I hope he will adduce the evidence for his assertion. Mr. Brook had not found this to be so when he reported upon the food of this fish for the Scottish Fishery Board, and indeed only the youngest Cod ever frequent the tidal waters to which *A. mesembryanthemum* is confined. Further, although *Pagurus bernhardus*, when not associated with an Anemone, is very frequently found in the stomachs of Cod and Haddock, I do not know a single instance of its having been found in the stomachs of the same fish when associated with one.

I am informed by Mr. Poulton that, in a work which is shortly to appear, he has included such animals as *Stenorhynchus* and *Caddis worms*, which disguise their appearance with foreign bodies simply in order to escape identification by enemies, in a group to which he gives the very convenient name "allocryptic." Animals which trust rather to the offensive than to the inconspicuous character of the foreign bodies with which they associate themselves he terms "allosematic" (σῆμα, a sign).

It is obvious that the allosematic method of protection is all but perfect, since it is largely free from the loss due to experimental tasting attendant upon the method of a purely warning appearance ("autosematic"). WALTER GARSTANG.

Plymouth, March 21.

Sea-bird Shooting.

Is it not time that something more was done to stop the wholesale slaughter of our sea-birds? During the past winter the havoc has been terrible, and unless some restraint is imposed we may expect before long to find our shores denuded of their white wings. When the birds had no value, there was a limit, though a wide one, to their destruction, because of the cost of killing them; but recently a large demand has sprung up for their skins, and an organized traffic is now carried on in the carcases.

The shooter gets from threepence to sixpence per bird from the amateur dealer, and for the sake of this paltry sum (surely the birds are worth more to us alive than this!) there is not a sporting lounger on the coast who can possess himself of a gun who does not kill every bird which can be reached either from the shore or from a boat. The gulls are pursued, I am told, even as far as the Dogger Bank.

The beautiful kittiwake is the greatest sufferer. One of the dealers boasted to me the other day that he had passed "nearer ten than nine thousand dead birds through his hands this season, chiefly kittiwakes." He added that he had got *804 carcases in one batch from one sportsman.*

From inquiries, I judge that this person's trade represents about one-third of the dead birds which have been sent away from our little town this season. I know the traffic is carried on at other points, and no doubt this is but an example of what is going on all round our coast. When we consider that the carcases which can be secured represent only a fraction of the birds killed or injured, we gain some idea of the extent of the mischief. Indeed, during the past month it has been possible to take a long walk along our shore without seeing a single sea-gull. Who wishes to see a blank seascape?

Now, surely, we all have equal rights in these graceful birds, and the numerous class who love to see them alive deserve as much consideration as the mischievous minority whose pleasure it is to destroy them! It is not as though these latter were worthy persons, compelled to a cruel employment for their daily bread: they are, on the contrary, nearly all of a class who deserve no sympathy—of a comfortable class who, I verily believe, would shoot their next-door neighbours if they could do so with impunity, and could dispose of the carcases! Just imagine the new variety of "sport" which one of them described to me not long ago! He said you could catch the gulls at sea by baiting a floating fishing-line with liver, and in this way, though you did not get quite so many as with a gun, you had far better *fun*, especially from the kittiwakes, as they are wonderfully "game," and, when they feel the hook, "flacker about and scream like a child"!

Is it too much to ask that our Legislature, which has spent so much time in the past on laws in the interests of the so-called "preservers" of game, will do something, and that speedily, in the interests of those who would fain be truly preservers of the sea-birds? At least they should extend the protection afforded to "game" to these noble birds, and order that those who shoot them shall pay a heavy license for their despicable sport, and those who deal in the dead carcases a still heavier.

And nothing in this matter must be left to local authorities. In seaside places self-interest vitiates the sentiment on this question. The fisherman finds it easier to earn money by letting his boat to the "sportsman" than by his legitimate productive industry; the tradesman fears to lose these men's custom; and the gentry, mostly supporters of "sport," are perhaps not sorry to have such an excellent safety-valve for guns which might otherwise poach on their preserves; and besides, there is in Yorkshire a semi-political aspect to the matter. Thus it has happened that of late years the clause in the (so far as it goes) excellent "Sea-birds Preservation Act" of 1869, which permits a lengthening of the close time under certain conditions, has been rendered

nugatory through the action of our county magistrates, who have refused to present the requisite petition to the Home Office. They must have been aware that their action doomed innumerable young birds to death by starvation, since the cliff-climbers collect the eggs until July (a perfectly legitimate industry, by the way, carried on by hard-working men, and producing valuable food), and thus render it impossible for the majority of the birds to get their young reared by the 1st of August.

And, in consequence, whenever during August I go on the shore under the great cliffs where the birds breed, my ears are filled with the melancholy "piping" of the starving helpless young, dying slowly on the ledges, whose parents have been shot—for sport, or threepence. G. W. LAMPLUGH.

Bridlington Quay.

Locusts.

WITH reference to the flight of locusts which passed over the steam-ships *Golconda* and *Clyde* in the Red Sea about November 25 last, it would be interesting to ascertain to what species they belong. The past year, 1889–90, has been marked in India by the invasion of locusts belonging to the species *Acridium peregrinum*, which, starting, it is believed, about the end of the hot weather (May or June), from the sand-hills of Western Rajputana, have, during the past six months, spread in vast numbers over the whole of Sind, Rajputana, the Punjab, North-West Provinces, and Oudh, besides penetrating sporadically into Guzerat, Ahmedabad, Baroda, Khandesh, and parts of Central India, a stray flight even appearing in the Kistna district of the Madras Presidency.

This insect, which is supposed to be the *locust* of the Bible, and which is undoubtedly the one that periodically invades Algeria from the Sahara, though it is altogether distinct from the locust *Stauronotus maroccanus*, of which so much has been heard in Algeria during the past two years, is likely to be the species which was observed in the Red Sea. To ascertain the point, however, with certainty, it is essential that specimens, which I am told fell upon the deck of the ship *Clyde* in considerable numbers, should be examined and determined entomologically, and my object therefore in addressing you is to endeavour to obtain some of the speci mens for comparison with those which have invaded India.

It is worthy of notice that in 1869 when Rajputana suffered considerably from locusts, vast swarms were also observed by ships passing through the Red Sea, and it would therefore be interesting to learn to what extent 1869 and 1889 were years of locust invasion in the intervening countries of Arabia, Persia, and Biluchistan. It is much to be regretted that in 1869 neither the locusts found in Rajputana nor in the Red Sea appear to have been preserved or determined, and their identity therefore cannot be definitely established. E. C. COTES.

Indian Museum, Calcutta, February 28.

THE ROYAL METEOROLOGICAL SOCIETY'S EXHIBITION.

THE eleventh Annual Exhibition of the Royal Meteorological Society was held at the Institution of Civil Engineers on March 18 and three following days. Each Annual Exhibition is devoted to some special branch of meteorology, which is illustrated by specimens of all known instruments (or drawings and descriptions of the same) that have been employed in its investigation. This year's Exhibition was illustrative of the application of photography to meteorology. Photographic meteorological instruments are not numerous, and those used for recording the indications of the barometer, thermometer, and electrometer are very costly and delicate, and are only made to order. The number of instruments in the Exhibition was consequently less than in previous years, but this deficiency was fully made up by the large and highly interesting collection of photographs of meteorological phenomena.

The earliest application of photography for the continuous registration of the barometer, &c., was made by Mr. T. B. Jordan, of Falmouth, in 1838. His plan was to furnish each instrument with one or more cylinders containing scrolls of photographic paper. These cylinders were made to revolve slowly by a very simple connection with a clock, so as to give the paper a progressive movement behind the index of the instrument, the place of which was registered by the representation of its own image.

In 1846, Mr. Charles Brooke and Sir Francis Ronalds each brought forward a method for the registration of magnetic and meteorological instruments by means of photography. The methods are those now in use, the former at the Royal Observatory, Greenwich, and the latter at the Observatories of the Meteorological Office.

Although these instruments were not shown, they were fully illustrated by photographs and drawings. A number of the barograms and thermograms were exhibited by the Astronomer-Royal and the Meteorological Council, showing the passage of storm centres, and sudden changes of temperature and humidity. A set of barograms from various parts of the world was exhibited by the Meteorological Council, showing the barometric oscillation due to the Krakatão eruption, August 1883. The thermogram at Kew on May 8, 1871, showed a fall of about 20° of temperature during a thunderstorm at 4 p.m.

Mr. Symons exhibited a photographic scale showing the intensity of sunlight during the solar eclipse of July 18, 1860; and the Kew Committee showed the chemical photometer devised by Sir H. Roscoe in 1863. Mr. J. B. Jordan exhibited his experimental instrument for recording the intensity of daylight, and also the three patterns of his sunshine recorder. Similar instruments designed by Dr. Maurer, of Zürich, and Prof. McLeod, were also shown. Prof. Pickering sent a photograph of his Pole-star recorder, in use at the Harvard College Observatory, U.S.A., for registering the cloudiness during the night. This instrument consists of a telescopic objective attached to a photographic camera and directed to the Pole-star; the camera is provided with very sensitive plates which are inserted in the evening, and a shutter, worked by an alarm clock, is closed before dawn. If the sky be clear during the night, the plate, after development, shows a semicircle traced by the revolution of the star around the North Pole, but if clouds have passed across the star, the trace is broken.

The photo-nephograph designed by Captain Abney for the registration of the velocity and direction of motion of clouds was exhibited by the Meteorological Council, as well as a model showing the manner in which the pair of photo-nephographs are mounted for use at the Kew Observatory. One of the instruments is placed on the roof of the Observatory, the other being at a distance of 800 yards; the observers at each end are in telephonic communication. Both cameras being oriented with reference to the same point of the horizon, the distant observer is instructed as to the direction and elevation of his instrument. The chief observer controls the exposure, both cameras being exposed simultaneously; another pair of plates are exposed after an interval of one minute. A slide rule designed by General R. Strachey for obtaining the height and distance of clouds from the pictures yielded by the cloud cameras was also exhibited, as well as photographs of an experimental apparatus designed by Mr. G. M. Whipple for the same purpose.

The Exhibition included a large and interesting collection of photographs of clouds. Padre F. Denza sent a set of 80 cloud photographs which had been taken during the past twelve months at the Specula Vaticana, Rome. M. Paul Garnier exhibited a magnificent set of 17 large photographs of clouds taken at his observatory, Boulogne-sur-Seine, Paris. These are the best photographs of clouds that have been seen in this country, and they were consequently very much admired. M. Garnier has not yet explained the method he adopts for obtaining such beautiful pictures. Dr. Riggen-

bach, of Basle, showed some photographs of cirrus clouds taken by reflection from the surface of the Lake of Sarnen. In this case the surface of the water acts like a polarizing mirror, and extinguishes the sky light. Photographs of clouds were also exhibited by Mr. Clayden, Dr. Drewitt, Dr. Green, Mr. Gwilliam, Mr. Harrison, Mr. McKean, Messrs. Norman May and Co., Mr. H. C. Russell, and Mr. Symons. Mr. H. P. Curtis, of Boston, U.S.A., sent a valuable and highly interesting collection of photographs, showing the devastation caused by the tornadoes at Rochester, Minnesota, on August 21, 1883, and at Grinnell, Iowa, on June 17, 1884. After seeing these photographs, some idea can be formed of the immense destruction wrought by these terrible scourges, which so frequently visit various parts of the United States. Mr. Curtis also exhibited three photographs of the tornado cloud; two of these were taken at Jamestown, Dakota, on June 6, 1887, when the cloud funnel was 12 miles to the north; the third, which was taken in New Hampshire, during the storm on June 22, 1888, shows the spiral-shaped funnel trailing at a considerable altitude in the air.

Many interesting photographs illustrating meteorological phenomena were exhibited. These included floods, snow-drifts, hoar-frost, frozen waterfalls, &c. A large number of photographs of flashes of lightning taken during the last twelve months were also shown, as well as some photographs of electric sparks, taken by Mr. Clayden and Mr. Bidwell, which explain the formation of dark images of lightning-flashes.

Mr. Clayden exhibited a very interesting and instructive working model, showing the connection between the monsoons and the currents of the Arabian Sea and the Bay of Bengal.

Mr. Dines showed a model of the whirling machine used by him at Hersham for testing anemometers and for experiments on wind-pressure; he also exhibited a remarkable curve showing the normal component of the wind-pressure upon a sloping surface 1 foot square, the normal pressure being taken as 100, and the pressure at various angles of inclination being expressed proportionately. Mr. Munro sent two instruments which he has recently constructed in conjunction with Mr. Dines. The first is for showing the velocity of the wind. The shaft of an anemometer is connected with the shaft of the instrument, and in turning works a small centrifugal pump, thus raising the level of the mercury in the long cistern. The deflection of the pendulum from the vertical position is proportional to the rate of turning, and thus gives a uniform scale. The second instrument is for showing the pressure of the wind from a velocity anemometer. The arrangement is the same as in the preceding instrument, but the fall of the float in the small circular cistern is proportional to the square of the velocity and therefore to the wind-pressure, thus giving a scale of pressure with the divisions at uniform distances.

Mr. Hicks exhibited Draper's self-recording metallic thermometer; a mercurial minimum thermometer with lens front; and a radial scale thermometer. Mr. Long showed Trotter's compensating thermometer for taking temperatures at any distance; and Mr. Denton exhibited his clinical thermometer case with new spring-catch.

WILLIAM MARRIOTT.

THE ORIGIN AND COMPOSITION OF THE FLORA OF THE KEELING ISLANDS.

At intervals I have contributed to NATURE the results of the more recent investigations of insular floras, more especially in relation to the dispersal of plants by ocean currents, birds, and winds; and now, through the courtesy of the author and Captain Petrie, Honorary Secretary of the Victoria Institute, I am able to furnish a commentative summary of a lecture[1] by Dr. H. B. Guppy, on the flora of the Keeling Islands.

It is hardly necessary to mention that Darwin visited these islands in 1836, except in connection with the fact that Dr. Guppy's visit was in a measure an outcome of that event. In 1878, Mr. H. O. Forbes spent some time there, and extended our knowledge of the flora. Primarily, no doubt, the coral-reef question took Dr. Guppy to the scene of Darwin's early labours, though he was probably not less interested in the flora, having been stimulated by practical botanizing in the Solomon Islands a few years previously; and a stay of nearly ten weeks enabled him to elucidate many points that were either obscure or conjectural.

Mr. John Murray, of the *Challenger* Expedition, found funds for Dr. Guppy's mission, and he presented to the Kew Herbarium the collections made of dried plants and drifted seeds and fruits; and there, such of them as were not already familiar to Dr. Guppy, and of which the material was sufficient, were named, and a set incorporated.

For the sake of brevity it will be better to describe what Dr. Guppy has accomplished, rather than follow him through his account of it.

Specimens were taken of all the different species of plants found in a wild state in the islands; notes made of the conditions under which they occurred, of their relative frequency, of their chances of propagation, and of their natural enemies, besides other particulars. In addition to seeds, or fruits containing the seeds, of the plants actually established on the islands, many others were picked up on the beach, where they had been deposited by the waves. Whilst most of these were in various stages of decay, others were actually germinating, and the question arose, Why had they not succeeded in obtaining a footing? As we shall presently learn, this question was easily answered.

Another point on which we had little trustworthy information was the length of time various seeds of essentially littoral and insular plants would bear immersion, or, rather, flotation, in sea-water without losing their vitality. With the exception of a few isolated instances of seeds having germinated after having been carried across the Atlantic to the western coast of Europe, very little was known, because the majority of the seeds experimented with by botanists at home did not belong to this class of widely-spread plants. Dr. Guppy instituted experiments on the spot, and although his time was too short to determine the extreme limits of endurance of the various seeds, he was able to prove that certain kinds germinated freely after being thirty, forty, or fifty days in sea-water. Again, he observed that some seeds that do not readily float, or only for quite short periods, are conveyed hither and thither in a variety of ways—such as in the cavities of pumice-stone, and in the crevices of driftwood.

From all available evidence, it is almost absolutely certain that there were no permanent inhabitants of the Keeling Islands till about the end of the first quarter of the present century; and from the most trustworthy accounts the islands were covered with vegetation, the coco-nut largely preponderating in the arboreous element. Indeed, as the outer part was almost entirely coco-nut, it seemed, as Darwin says, at first glance to compose the whole wood. But there is evidence that there were large "forests" in the interior of the islands, consisting mainly of the iron-wood, *Cordia subcordata*. The largest island is said to be only about five miles long; and the group is between 600 and 700 miles from the nearest land, excluding the small Christmas Island.

Already at the time of Darwin's visit in 1836, the islands were in the possession of Captain Ross, the

[1] "The Dispersal of Plants, as illustrated by the Flora of the Keeling or Cocos Islands." A Paper read at a meeting of the Victoria Institute on Monday, February 3, 1890, by Dr. H. B. Guppy.

grandfather of the present proprietor, and coco-nut planting was progressing. Since then most of the available ground has been cleared of other vegetation and planted with coco-nut trees, so that the wild vegetation is nearly limited to an external fringe, and this often broken. In North Keeling, about fourteen miles distant from the main group, which was not visited either by Darwin or Forbes, there was still sufficient of the original vegetation left for Dr. Guppy to form an idea of what it was generally before it was cleared away for cultivation. Darwin's investigations had the effect of arousing the interest of Captain Ross in the natural history of the group, and this interest has been inherited by his descendants, who have greatly aided subsequent travellers by their hospitality and by their knowledge of local phenomena. Darwin collected or noted about a score of different species of wild plants, and this number has now been doubled by Forbes and Guppy.

This brings us to the results of Guppy's own investigations, the most interesting and important being those relating to the capabilities of certain plants, notably the coco-nut, to establish themselves on coral islands, as some writers of repute have strongly contested the possibility of it, and there can be little doubt that the coco-nut and other plants having large seeds obtain a footing only under exceptional circumstances, such as being buried by the sands washed over them in heavy gales.

Foreign coco-nuts are frequently cast ashore on the Keeling Islands, where they sometimes germinate, but the crabs invariably destroy the sprouting nut. Suppose, however, a period when crabs were less numerous, and the chances are not so very remote of some of the growing nuts escaping them. Again, Mr. Forbes cites an instance in which the crabs may even facilitate the establishment of the coco-nut, for he observed that the crabs sometimes burrow so near the surface that the nuts occasionally break through and find favourable conditions for growth. Should they escape the crabs in their earliest infancy, they are safe. Many other plants are now prevented by the crabs from establishing themselves on the Keeling Islands. Dr. Guppy says:—

"I have been informed by the proprietor that sometimes when a large amount of vegetable drift has been stranded on the beach, a line of sprouting plants may be shortly observed just above the usual high-tide mark; but the tender shoots are soon eaten by the crabs, and in a little time every plant is gone. Many of the seeds that germinate on the beach are beans, varying in size from those of *Entada scandens* downward. They form one-third of the vegetable drift."

Indeed, the crabs are so numerous that Mr. Ross has failed in many attempts to raise plants of some of these things in his garden. One flourishing *Entada scandens* and a sickly *Calophyllum Inophyllum* were all the reward of much trouble in this direction. The huge square fruits of *Barringtonia speciosa* are often thrown up, and the seed germinates, but very few escape the crabs. This tree had not established itself in North Keeling, though in August 1888, Dr. Guppy observed two seedlings about eighteen inches high, and they owed their preservation, it was supposed, to the circumstance of the fruits having been concealed when the seeds germinated by the bed of fine drift pumice that had been deposited on the shores of the lagoon after the Krakatão eruption.

Particulars are given of the incipient germination and early destruction of *Carapa*, *Nipa*, *Cycas*, and other seeds. Of course, the clearing of the original vegetation and subsequent cultivation, and the incidental or intentional introduction of various birds and animals, and the migration of the myriads of sea-birds that formerly inhabited the islands must all be taken into consideration. Yet no species of plant ever known to grow wild there has become quite extinct, an evidence of their tenacity of life under unfavourable conditions.

Dr. Guppy's additions to the Keeling flora include the following plants, which he regards as having formed part of the original vegetation, judging from the conditions under which he found them: *Calophyllum Inophyllum*, *Thespesia populnea*, *Triumfetta subpalmata*, *Suriana maritima*, *Canavalia obtusifolia*, *Terminalia Catappa*, *Barringtonia speciosa*, *Sesuvium Portulacastrum*, *Ipomœa grandiflora*, *I. biloba* (*I. pes-capræ*), *Premna obtusifolia*, and *Hernandia peltata*. Their general distribution fully justifies this deduction.

The experiments on the vitality of seeds after forty to fifty days in sea-water were necessarily of a limited character, but they established the fact that the following germinated: *Cordia subcordata*, *Hernandia peltata*, *Guettarda speciosa*, *Thespesia populnea*, *Scævola Kœnigii*, *Morinda citrifolia*, and *Tournefortia argentea*. Every seed of the last named germinated after forty days', and half of the seeds of *Morinda* after fifty-three days' immersion. Dr. Guppy calculates that a surface current of only one knot an hour would convey drift a distance of 1000 to 1200 miles during these periods. From the fact that almost all the drift is thrown up on the eastern and southern coasts, it is assumed that the bulk of it comes from the Malay Archipelago, and perhaps some from the north-west coast of Australia. This is borne out by the general distribution of the established Keeling plants, as well as by the other seeds and fruits that are stranded there.

Among the latter may be mentioned *Pangium edule*, *Heritiera littoralis*, *Erythrina indica*, *Mucuna* spp., *Dioclea reflexa*, *Cæsalpinia Bonducella*, *Cerbera Odollam*, *Quercus* spp., and *Caryota*.

Carpophagous pigeons have played no recognizable part in the flora of the Keeling Islands.

In his forthcoming book Dr. Guppy will doubtless give all the details of his observations in a more connected and systematic form.

W. BOTTING HEMSLEY.

NOTES.

TO-DAY the honorary freedom and livery of the Turners Company are to be conferred on Sir John Fowler, K.C.M.G., and Sir Benjamin Baker, K.C.M.G., "in recognition of their distinction and eminence as engineers, earned by many great works at home and abroad, especially the design and construction of the Forth Bridge, one of the greatest triumphs of British engineering in the Victorian age."

SIR JOHN KIRK, F.R.S., AND SIR WILLIAM TURNER, F.R.S., Professor of Anatomy in the University of Edinburgh, have been elected members of the Athenæum Club, under the rule which provides for the annual election of a certain number of persons of distinguished eminence in science, literature, or the arts, or for public services.

MR. T. KIRKE ROSE, Associate of the Royal School of Mines, has obtained the appointment of Assistant Assayer at the Royal Mint, by competition among selected candidates. It is a post of some importance, and the salary rises from £350 to £450, with an official residence in the Mint. After an unusually brilliant career at the Royal School of Mines, Mr. Rose was engaged as metallurgist and assayer to the Colorado Gold and Silver Extraction Company in Denver. It is to be hoped that he will afford valuable assistance to Prof. Roberts-Austen in preserving the standard fineness of our coinage with the remarkable degree of accuracy that generations of assay masters have attained.

SIR HENRY ROSCOE has introduced into the House of Commons a Technical Education Bill, which is intended to clear up any doubt as to the legality of the provision of technical

and manual instruction in public elementary schools. The following are the provisions of the measure :—(1) The managers of any public elementary school may provide technical or manual instruction for the scholars in that school, either on the school premises or in any other place approved by the inspector, and attendance by the scholars of the school at such instruction shall be deemed to be attendance at the public elementary school. (2) The conditions on which Parliamentary grants shall be made in aid of technical or manual instruction in public elementary schools, shall be those contained in the Minutes of the Education Department and of the Science and Art Department in force for the time being. (3) The expression "technical instruction" and "manual instruction" shall have the same meaning as in the Technical Instruction Act (1889).

LAST week Dr. Farquharson asked the President of the Board of Trade whether he was aware that much dissatisfaction existed among scientific men as to the sufficiency of the tests used in the mercantile marine for the detection of colour-blindness, and whether he would appoint a committee of experts to advise the Government on this important question. In reply, Sir Michael Hicks-Beach said he was sensible of the importance of the matter, and had been in communication with the Royal Society upon the subject; and he was happy to state that "that valuable institution had appointed a committee to consider the whole question of colour-blindness."

THE meetings of the Institution of Naval Architects are now being held in the hall of the Society of Arts; the chair being occupied by Lord Ravensworth, the President of the Institution. The following is the programme of proceedings :—Wednesday, March 26, morning meeting, at 12 o'clock : (1) Annual Report of Council; (2) election of Officers and the Council; (3) alteration of rules relating to election of Vice-Presidents; (4) Address by the President; the following papers were then to be read and discussed—notes on recent naval manœuvres, by W. H. White, F.R.S., Director of Naval Construction, Vice-President; the Maritime Conference, by Rear-Admiral P. H. Colomb, R.N. Thursday, March 27, morning meeting, at 12 o'clock : on leak-stopping in steel ships, by Captain C. C. Penrose Fitzgerald, R.N.; strength of ships, with special reference to distribution of shearing stress over transverse section, by Prof. P. Jenkins; steatite as a pigment for anti-corrosive paints, by Frank C. Goodall. Evening meeting at 7 oclock : on the evaporative efficiency in boilers, by C. E. Stromeyer; on the application of a system of combined steam and hydraulic machinery to the loading, discharging, and steering of steam-ships, by A. Betts Brown; the revolving engine applied on board ship, by Arthur Rigg. Friday, March 28, morning meeting, at 12 oclock : on the variation of the stresses on vessels at sea due to wave-motion, by T. C. Read; spontaneous combustion in coal ships, by Prof. Vivian Lewes. Evening meeting, at 7 o'clock : on the screw propeller, by James Howden; experiments with life-boat models, by J. Corbett.

THE Geologists' Association have made arrangements for an Easter excursion to North Staffordshire. It will last from April 3 to 8, and the head-quarters will be the North Staffordshire Hotel, Stoke-on-Trent, except on Saturday and Sunday nights, when the Association will stay at the Red Lion, Leek.

A CONFERENCE of the Camera Club, under the presidency of Captain de W. Abney, was held last week at the Society of Arts. Lord Rayleigh gave an account of instantaneous photography by the light of the electric spark. He stated that he had been experimentalizing in taking photographs of minute jets of water as from a bottle. He exhibited on the sheet, by means of the electric light, photographs of jets of water taken in less than the 100,000th part of a second. In the course of the discussion following the demonstration and explanations by Lord Rayleigh, Mr. Trueman Wood spoke of the new application of electricity to the photographic art in fixing for study natural phenomena. The chairman, in giving the thanks of the meeting to Lord Rayleigh, referred to some photographs taken in less than the 100,000th part of a second under the name of a "photographic untruth." Captain Abney dealt with the untruth of form, which photography gave when judged by light and shade, a subject which could only be explained by series of drawings on the black-board and shadows cast upon the sheet.

THE Royal Microscopical Society has received from Dr. E. Abbe, of Jena, one of the new apochromatic $\frac{1}{10}$th microscope objectives recently produced at Zeiss's optical works, Jena, under Dr. Abbe's superintendence. The aperture is the highest hitherto attained, being 1·6 N.A., whereas the highest point previously reached by Dr. Zeiss was 1·4 N.A., so that the clear gain of aperture is 20 per cent. The advantage of this increase is shown by the perfection of the images obtained in photomicrographs produced by the new objective in the hands of Dr. Henri Van Hewick, Director of the Jardin Botanique, Antwerp, specimens of whose work were exhibited at the last meeting of the Royal Microscopical Society. At this meeting it was announced that Dr. Dallinger, F.R.S., had consented to join a committee appointed by the Council of the Royal Microscopical Society, to make a special report on the new objective.

AT the fortnightly meeting of the Royal Horticultural Society, on Tuesday, M. Henri de Vilmorin, President of the Botanical Society of France, delivered a lecture on salads, mentioning that in England we neither eat nor grow so many plants for salad as in France. He dwelt upon the nutritive value of salads due to the potash salts, which, though present in vegetables generally, are eliminated in the process of cooking. He then enumerated the various plants which are used in salads in France—namely, the leaves of lettuce, corn-salad, common chicory, barbe de capucin, curled and Batavian endives, dandelion in its several forms of green, blanched, and half-blanched, water-cresses, purslane in small quantities, blanched salsify-tops of a pleasant nutty flavour, witloof or Brussels chicory, the roots of celeriac, rampion, and radish, the bulbs of stachys, the stalks celery, the flowers of nasturtium and yucca, the fruit of capsicum and tomato, and, in the south of France, rocket, picridium, and Spanish onions. Various herbs are added to a French salad to flavour or garnish it, such as chervil, chives, shallot, and borage flowers. In addition, many boiled vegetables are dressed with vinegar and oil. M. de Vilmorin then showed specimens of dandelion, barbe de capucin, and witloof, both varieties of chicory, which he recommended to the notice of English gardeners as most useful and palatable. He mentioned that from a ton to a ton and a half of witloof is daily brought to the Paris market from Brussels, where it is grown in the greatest perfection. Specimens of English salads grown in the month of March, and consisting of corn-salad, lettuce, and blanched chicory, were sent from the Marquis of Salisbury's gardens at Hatfield. Among the other exhibits was a quaint orchid (*Cœlogyne pandurata*), a native of Borneo, sent from Kew Gardens. The flower is bright green, like the colour of forced lilac-leaves, with a dull jet-black blotch and lines on the lip.

AT the meeting of the Royal Botanic Society on Saturday, it was announced that the donations received included an interesting collection of seeds from the gardens of Mr. Thomas Hanbury, at Mortola, on the coast near Ventimiglia, Italy, with printed catalogues of the great variety of plants and trees from all climes growing in the garden—more than 4000 named species.

BARON DE LISSA, the pioneer planter of British North Borneo, arrived at Sandakan in January last. The official *Gazette* of British North Borneo says that the Royal Geographical

Society of Australia have forwarded to the Baron a draft for £100 towards the expenses of obtaining some information regarding the fauna and flora of Kina Balu and its neighbourhood. Baron de Lissa has placed himself in communication with the Governor on the subject, and is endeavouring to secure the services of a well-known geologist and naturalist who is residing at Sandakan.

THE following science lectures will be delivered at the Royal Victoria Hall:—April 1, an hour with the telescope, by J. D. McClure; April 15, the colours of a soap bubble, by John Cox.

IT is pleasant to turn over the pages of the handsome new edition of Darwin's famous "Voyage of a Naturalist" (Murray). The text is well printed, and no one can fail to enjoy the admirable illustrations contributed by Mr. R. T. Pritchett. In a prefatory note Mr. Murray explains that most of the views given in the work are from sketches made on the spot by Mr. Pritchett, with Mr. Darwin's book by his hand.

IN a few days the first part of a new work on the theory of determinants, by Dr. Muir, of Glasgow, will be published by Messrs. Macmillan and Co. It presents the subject in the historical order of its development, beginning with the brilliant but unfruitful conceptions of Leibnitz in 1693, and carrying the record forward to 1841, the year of the appearance of Cayley's first paper.

MR. H. A. MIERS, of the Natural History Museum, is engaged upon a text-book of mineralogy, which will be published by Messrs. Macmillan and Co.

LAST week (p. 478) we noted that at the meeting of the Royal Society of Edinburgh, on February 28, Dr. John Berry Haycraft had communicated the results of some recent investigations on voluntary muscular contraction. Dr. Haycraft's observations are interesting both to physiologists and to physicists. Where a muscle is stimulated by an electrical shock, all the fibres of the nerve receive the same stimulus, and all the fibres of the muscle to which the nerve passes contract together, and in the same way. This is not the case when a muscle contracts on receiving a natural nerve stimulation, starting either as a result of volition or of reflex action. The central nervous system seems unable to affect all the fibres of a muscle, through the numerous nerve fibres passing to it, in such a manner that they all shall contract exactly in the same way. The reason for supposing this to be the case is the fact, observed by the author, that fascicular movements are always present within a muscle during a voluntary or a reflex contraction, so that tracings taken from different parts of the same muscle invariably differ from each other. The experiments were conducted both upon the human masseter and the gastrocnemius muscle of the frog. These fascicular movements occurring within it will prevent any muscle from pulling with perfect steadiness on any lever or other registering apparatus, and the tracings taken by means of such apparatus will show oscillatory waves, often very rhythmical in their appearance. Many observers have concluded from an examination of these tracings that they indicate that the central nervous system discharges impulses into the muscle at a rate corresponding with that of the oscillations observed. Thus some observers find 20, others 10 oscillations per second in the muscle curve, and they consider that the nervous system discharges into the muscle at these rates. The author finds that the fascicular movements just described as occurring within the muscle itself account fully for the oscillations seen, the irregular aperiodic movements of the muscle compounding themselves with the period of oscillation proper to the registering apparatus itself, for by varying the instruments used, the resultant curves may be varied at will, slow oscillations appearing when using instruments of slow period, quick oscillations when using instruments of quick period. The author suggests that these fascicular movements probably account for the production of the muscle sound, which Helmholtz long ago pointed out was chiefly an ear-resonance sound. This, of course, could readily be evoked by any slow aperiodic movement, and the fascicular movements within the muscle must at any rate assist in producing it. These fascicular movements may, perhaps, account for the results obtained by Lovén, with the capillary electrometer, for it is more probable that he was registering the period of his own instrument than that the muscles were twitching at the slow rate of 8 times per second. If these conclusions are correct, there remains little to be said in support of the theory generally accepted that the nervous system normally discharges nerve impulses into the muscles like shots quickly fired from a revolver. It may be that this is the case, but the subject requires more extended investigation before any definite conclusions can be arrived at.

THE St. Petersburg Academy of Sciences has issued the Report for 1889, which was read at the annual meeting on January 12. The Report contains a valuable analysis of the scientific work done by the members during the year. In mathematics, Prof. Tchebysheff's applications of simple fractions to the investigation of the approximate value of the square root, and M. Ishmenetsky's work on the integration of symmetrical differential equations, are especially worthy of note. In astronomy, we notice O. A. Backlund's researches on the influence of temperature upon refraction. In physics, M. Khwolson made an attempt at a mathematical investigation of the extremely complicated laws of dispersion of light in milk-coloured glasses. The exploration of earth magnetism has made marked progress, both as regards the theory of diurnal variations and the measurement of magnetical elements in Caucasia and Siberia. Besides theoretical work in meteorology, the Central Physical Observatory has extended its system of weather-forecasts. Much interesting work has been accomplished in geology, Baron Toll having brought out the first volume of the geological part of the work of the expedition to the New Siberia Islands. In the botanical department the chief event was the publication of two parts of Prof. Maximowicz's description of the plants brought from Central Asia by Przewalsky, as well as the flora of Western China, as represented in the valuable collections brought by M. Potanin. Highly interesting work was done in zoology by Prof. Famintzyn.

WHEN the sun sets in the sea, a curious appearance, as of a bluish-green flame, is sometimes observed. This has been thought to be due to the light passing through the crests of waves. But Prof. Sohncke (*Met. Zeits.*) considers this view disproved by such an observation as that recently made by Prof. Lange at a watering-place on the Baltic. Shortly before sunset, the disk was divided in two by a thin strip of cloud; and just as the upper part disappeared under the cloud, the blue flame was observed. Thus the cause appears to be in the air, not in the sea. It is a case of atmospheric refraction. And as a planet, seen near the horizon with a good telescope, appears drawn out into a spectrum, with the more refracted blue-violet end higher than the red, so the last visible part of the sun furnishes the blue-violet end of a spectrum. But it would be interesting, Herr Sohncke remarks, to determine more precisely the conditions of this not very frequent phenomenon. Perhaps it requires merely great transparency of air, as only in this case would the last ray be able to give a spectrum sufficiently intense in its blue region.

THE Report of the Meteorological Council for the year ending March 31, 1889, has been published, and describes the work of the Office under three heads. (1) Ocean Meteorology. The

number of logs received from ships was 189; of these 80 per cent. were classed as "excellent," being a greater percentage of excellence than has been reported for some years. The discussion of the meteorology of the Red Sea is still in progress, and the work is well advanced. Charts of barometrical pressure for four representative months for the various oceans have been issued, together with charts showing the mean barometrical pressure for the year, and the extent of range of irregular fluctuations, and considerable progress has been made in the construction of the current charts for the various oceans. As these works are cleared off, it is intended to undertake a discussion of the meteorology of the region from the Cape of Good Hope to New Zealand. (2) Weather Telegraphy. The work of this branch continues to increase, and the Daily and Weekly Weather Reports, in particular, have been extended and improved. Forecasts continue to be prepared three times daily, and special forecasts were issued during the hay-making season; the highest percentage of success of the latter was in the southern part of England, and the lowest in the north-east district. Storm warnings are issued to those places on the coast that desire to receive them. (3) Land Meteorology of the British Isles. The records from the Observatories and Stations of the Second Order are discussed and published. The Council have continued the annual grant of £100 towards the expenses of the Ben Nevis Observatory, and have received copies of the observations made there. They have also agreed to allow £250 a year to the proposed Observatory at Fort William, for five years, and to supply an outfit of an Observatory of the First Order, to be equipped with self-recording instruments. The Report also contains interesting notes on some results of an examination of the Atlantic charts published by the Office, and on the measurement of squalls shown on the traces of Robinson's anemometers.

A NEW alkaloid, to which the name taxine is applied, has been extracted and isolated by Drs. Hilger and Brande, of Erlangen, from the leaves, seeds, and young shoots of the yew tree (*Taxus baccata*). Lucas some time ago pointed out the existence of a narcotic partaking of the nature of an alkaloid in the yew tree, and Marmé has since described a mode of extracting it. Drs. Hilger and Brande have lately prepared large quantities of this alkaloid, and have at length satisfactorily determined its composition and its more important chemical properties. The leaves and seeds were first repeatedly treated with ether in order to extract as much of the alkaloid as possible. The extract was then subjected to distillation to remove the ether, and the residue agitated with water acidified by a little sulphuric acid. The acid washings were noticed to be strongly coloured, and this was found to be due to the high tinctorial power of a compound of taxine with sulphuric acid. The acid solution was then rendered alkaline by ammonia, and the precipitated alkaloid dried over sulphuric acid. After dissolving in ether, re-washing with acid and precipitating with ammonia several times, the alkaloid was obtained as a perfectly white powder of extremely bitter taste, and melting at 82° C. On heating in a glass tube the melted taxine partly sublimes as a white cloud which condenses in the colder part of the tube in the form of drops of oil which solidify on cooling. At the same time it evolves a most characteristic odour. It is very difficultly soluble in water, chloroform, or benzene, but readily in alcohol and ether. Concentrated sulphuric acid produces an intense purple coloration. Dilute acid solutions give precipitates with gold chloride, platinum chloride, and picric acid, and also even in very dilute solutions yield precipitates on the addition of caustic alkalies or ammonia insoluble in excess. Analyses show that the formula of taxine is most probably $C_{37}H_{52}O_{10}N$. It forms with acids salts readily soluble in water. The hydrochloride, sulphate, acetate, oxalate, and tartrate, have been prepared, likewise the double salts with the chlorides of platinum and gold. The hydrochloride is best obtained by passing hydrochloric acid gas through a solution of taxine in anhydrous ether, when the salt is at once deposited in good crystals. Analysis indicates the formula $C_{37}H_{52}O_{10}N.HCl$. The sulphate possesses the composition $(C_{37}H_{52}O_{10}N)_2H_2SO_4$, the platinochloride $(C_{37}H_{52}O_{10}N.HCl)_2PtCl_4$, and the aurochloride $(C_{37}H_{52}O_{10}N.HCl)AuCl_3$. A compound of taxine with ethyl iodide, of the composition $C_{37}H_{52}O_{10}N.C_2H_5I$, was also obtained by heating equal molecules of the alkaloid and ethyl iodide to 100° C. under pressure. This compound is also a crystalline solid soluble in water. As regards the constitution of the alkaloid, which from its high molecular weight must of necessity be extremely complex, it has only yet been ascertained that it belongs to the class of nitrile bases. The leaves of the yew tree were found to contain the largest quantity of taxine, the seeds containing a smaller but still by no means inconsiderable quantity of the alkaloid.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♀) from India, presented by Mr. McDowall Currie; a Ring-necked Parrakeet (*Palæornis torquatus* ♂) from India, presented by Miss Thornton Smith; two West African Love Birds (*Agapornis pullaria* ♂ ♀) from West Africa, presented by Mrs. Cyril Tatham; a Black-necked Stork (*Xenorhynchus australis*) from Malacca, two Peacock Pheasants (*Polyplectron chinquis* ♂ ♀) from Burmah, purchased.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on March 27 = 10h. 21m. 7s.

Name.	Mag.	Colour.	R A. 1890.	Decl. 1890.
			h. m. s.	° ′
(1) G.C. 2102	—	Blue.	10 19 29	−18 5
(2) 37 Leonis	5·7	Yellowish-red.	10 10 47	+14 17
(3) γ Leonis...	2	Yellowish-white.	10 13 54	+20 24
(4) α Leonis...	1	White.	10 2 30	+12 30
(5) 136 Schj.	6	Very red.	10 46 17	−20 46
(6) X Boötis...	Var.	Dull orange.	14 18 59	+16 49

Remarks.

(1) This is a very bright planetary nebula in the constellation Hydra. From its size and equable light, Smyth compared it to Jupiter. It is about 32″ in diameter, and its spectrum consists of bright lines. In 1868, Dr. Huggins recorded the presence of the three characteristic nebula lines, but Lieutenant Herschel only saw two of them. The spectra of planetary nebulæ are by no means difficult to observe, notwithstanding their generally small diameters. If no cylindrical lens be employed, the lines in some cases are considerably bright, and their shortness is no great drawback. Now that we know that there are a good number of lines in the nebula of Orion, it seems reasonable to expect that a careful search will reveal a greater number in other nebulæ. D_3 and a line about λ 447 are the next in order of brightness to the three chief lines and G in the visible part of the spectrum of the nebula in Orion, and these should therefore be first looked for. It should also be particularly noted whether the brightest line is perfectly sharp on both edges, or otherwise.

(2) This star has a spectrum of the Group II. type. Dunér states that the spectrum is rather feebly developed, all the bands being narrow. The bands 2 and 3 in the red are the strongest. The character of the spectrum indicates that the temperature of the star is probably higher than that of most of the members of the group, the spectrum approaching that of Aldebaran. In that case, a considerable number of lines may be expected. It will be remembered that in Aldebaran there is mainly a line spectrum, together with the remnants of the bands in the red.

(3) A star of the solar type (Gothard). The usual observations are required.

(4) This is a star of Group IV., showing several fine metallic lines in addition to those of hydrogen. The usual observations are required.

(5) The spectrum of this star is a fine one of Group VI. The usual carbon bands are wide and dark, and the subsidiary bands 4 and 5 are perfectly well seen (Dunér). It seems probable that favourable conditions of observation, which, unfortunately, are not common for low stars in our latitude, may reveal other secondary bands.

(6) This is another variable star of which the spectrum has apparently not been recorded. The period as determined by Baxendell is 121·4 days, and the magnitudes at maximum and minimum are 9·2 and 10·2 respectively. The maximum will be reached about April 5. (This is Baxendell's V Boötis.)

A. FOWLER.

CHARLES MARIE VALENTIN MONTIGNY.—It is with regret that we have to announce the death of Prof. Montigny, at Schaerbeek, on the 16th inst. Prof. Montigny was born on January 8, 1819, and was a member of the Royal Academy of Belgium, Astronomical Correspondent of Brussels Observatory, an officer of the Order of Leopold, and decorated with the civil cross of the first class. He is best known for his interesting researches on the scintillation of stars, which form the subject-matter of a series of papers communicated to the Brussels Academy. In the January number of *Himmel und Erde* a long description is given of the results of Montigny's observations, and the instrument he devised and used for the determination of the amount of scintillation on different nights, and for the same stars at different altitudes. It is well known that if a scintillating star is observed by means of an opera-glass or small telescope, and the instrument tapped, the star appears to move and not the instrument; if the instrument is kept vibrating, the star will appear to move in a closed curve, along which different colours repeat themselves. The scintillometer devised by the late Prof. Montigny for investigating these appearances consisted of a small disk which could be whirled round in front of the eye-piece so that the star appeared to describe a circle in the field of the telescope. The circumference of this circle was made up of a regular sequence of colours, of which blue, yellow, and red were predominant. If the rate of motion of the disk be known, then by counting the number of times the colours were repeated the number of changes of colour a second may be found. All the causes affecting the scintillation of stars were investigated, and the relation of the amount to the character of the spectrum, the state of the atmosphere, and the colour of the star, made the subject of inquiry. The results obtained by means of this ingenious instrument are important, and the whole work on scintillation done by the deceased astronomer stands as a fitting monument to his memory.

AN OBSERVATORY AT MADAGASCAR.—A new Observatory has been established at Tananarivo under the direction of the Jesuit fathers, and with the concurrence of the French Government. The site chosen is a hill a short distance to the east of the town, and about 4400 feet above sea-level, making the Observatory one of the highest in the world. It already possesses an equatorial, a meridian instrument, and all necessary apparatus for meteorological observations; and a photographic telescope will shortly be provided for solar observations.

THE ADMINISTRATION OF FOREIGN FISHERIES.

THE following notes[1] were drawn up at the request of the late Lord Dalhousie just before he became seriously ill. The failure of his health and his absence from home—before the sad bereavement and shock which terminated in his death—prevented him perusing them, though the substance of much that appears in the subsequent pages formed the theme of several conversations with him. His familiarity with the sea, his wide knowledge of the fisheries, his upright and generous bearing, and his sound judgment, would undoubtedly, if he had been spared, have been of infinite service to the Department (which, probably, sooner or later, he would have reorganized very thoroughly). No greater loss, indeed, has happened to the fisheries in recent times.

[1] For information on various points relating to the subject, I have to thank Profs. Alex. Agassiz, Hubrecht, Möbius, Lovén, and G. O. Sars, Herr von Behr, Drs. Anton Dohrn, Lindeman, Nansen, and Sauvage; while Mr. Hoyle kindly aided me with the Norwegian statistics.

The United States Fish Commission is managed by a Director, who is more or less autocratic and irresponsible; though in the case of the late Prof. Baird the Americans were extremely fortunate in having a Director possessed of great administrative power and tact, and who never utilized the resources at his disposal for personal display or advancement. However able this Director may be, the system has its disadvantages, and is less suitable than a mixed Commission of men of position, who would have an opportunity of expressing their views as to the work to be carried out. Moreover, the American plan is less safe than a responsible head—that is, a chief under the control of a Board or Commission of those who are not necessarily specially skilled. It is possible, indeed, that, as the fisheries are at present administered in the United States, a considerable expenditure of money and of time annually takes place, which under other methods might be curtailed. The practical advances made by the Americans have in the main been confined to the fresh-water fisheries—that is, the propagation of the salmon-tribe, carp, and other fluviatile and lacustrine forms. The Marine Department has not yet succeeded in making any noteworthy improvement in sea-fisheries, though much money has been spent, and a large Annual Report is regularly issued. This Report contains not only the work accomplished by the staff of the Department, but reprints and translations of papers relating to the fisheries of other countries. There is, therefore, a wide difference between the condition in this country (where the observations connected with the fisheries have often to be published by Societies or independent journals) and the lavish expenditure on the other side of the Atlantic.

In France, again, the management of the fisheries is exclusively vested in the Minister of Marine at the Bureau des Pêches. At the head is a Director charged by the State with the inspection of the fisheries. For the scientific study of the questions pertaining to the marine fisheries the chief station is at Boulogne—though the Minister of Agriculture, under whom the station was constructed, also gave a small subsidy to the Zoological Laboratory at Villefranche (Alpes Maritimes) for the study of diverse questions concerning fishes and oysters—and this was founded by a subsidy from the town and the Chamber of Commerce. The advances made by M. Coste and others in the fresh-water fisheries of France are too well known to need further attention. France is fortunate in having a series of excellent marine laboratories, at which considerable advances have already been made in regard to the food-fishes, and in collateral scientific subjects. The names of MM. Lacaze Duthiers, Giard, Marion, Barrois, Pouchet, Sauvage, and others, are sufficient guarantees that the work of the fisheries and cognate subjects will be worthily carried out.

In Norway there is no special Fishery Board, but the Governmental Department of the Interior manages both the marine and fresh-water fisheries. As yet only a general inspector for the latter has been appointed at a fixed salary. For each of the more important marine fisheries, however, a so-called *opsynschef* is engaged by the Government, to see to the administration of justice during the time the fishery is going on. Moreover, an annual grant of 16,000 kr. is granted to the Society for the Advancement of Norwegian Fisheries in Bergen. The aims of this Society, which has various branches in towns along the coast, are chiefly practical, such as the improvement of fishing implements, the most suitable and successful preparation of the fishery products, and other features. It also has a special department for the artificial hatching of the food-fishes, in connection with the laboratory at Arendal, on the southern coast. The expenses of this establishment are partly borne by the Society just mentioned, and partly by private subscription. It is at this laboratory that M. Dannevig has done so much good work in the artificial rearing of cod, oysters, and lobsters, in the former case having succeeded in keeping the fishes till the end of the second year, and when of considerable size (14–16 inches).

For strictly scientific investigations in connection with the marine fisheries the Storthing grants an annual sum of 4800 kr. These investigations have for many years been chiefly carried out by Prof. G. O. Sars, whose observations on the Lofoten cod-fisheries, and the development of the cod, are well known and justly esteemed, while, as a worthy son of a distinguished father, he has in other departments of zoology contributed largely to our knowledge. Other naturalists have also been engaged in the work, chiefly in regard to the herring fisheries. Prof. Sars, moreover, with a view of protecting the marine fisheries, has to report on every contrivance proposed,

and in regard to restriction in the use of certain fishing implements, besides giving his advice concerning the regulation of close seasons and similar subjects. He has to present to the Department his opinions on these matters before the proposals are brought in for the Storthing. In 1886 much discussion took place in the latter assembly concerning a more central management of the Fishery Department, and the establishment of a special office for a chief director for all the fisheries, together with a staff of subordinate inspectors. This arrangement is considered in Norway to be of considerable importance, but unfortunately no individual is known who unites in himself all the many qualifications for this important office. The following are the grants sanctioned for the financial year from July 1, 1886, to June 30, 1887, for the Fishery Institutions:—

(1) For practical scientific investigation regarding the sea fisheries, the last Parliament voted 4800 kr.[1]

It is proposed to increase this by 2400 kr., to be given to Hr. Lumholtz.

(2) As a contribution to the Society for the Encouragement of the Norwegian Fisheries, the last Parliament voted 16,000 kr., of which 4000 kr. were to be given to the affiliated Societies of Tromsö, Stift, and 2000 kr. to the Institution for Pisciculture in Arendal.

It is desired to increase this sum to 32,000 kr. for the coming year; the work of the Society depends upon this grant, because the fishermen cannot be expected to contribute much, and the needs of the Society are always increasing. The expenses for the coming year are estimated at 34,910 kr., of which 12,000 kr. will be needed for the regular expenses of the Society. It is proposed that the fisheries should be under a central direction with subordinate officials, and thus the Society would be relieved of a large part of its expenses.

The Department decided, however, that the grant should be retained at its original amount, 16,000 kr.

(3) For inspection and administration of the law at Lofoten cod-fishery, 31,950 kr. were voted.

(4) For increased police inspection of the mackerel-fishery at Uleholmene 200 kr. were voted.

(5) For increased police inspection of the spring cod-fishery in Namdal 1000 kr. were voted.

(6) For increased police inspection of the spring cod-fishery in Finmark 7200 kr. were voted.

(7) For increased police inspection of the spring cod-fishery in Söndmöre 3600 kr. were voted.

(8) For inspection and administration of the law at the herring-fishery 12,000 kr. were voted.

(9) For the encouragement of fresh-water fisheries 24,040 kr. were voted.

This sum it is desired to increase to 31,000 kr.

A. *Expenditure.*

			Kronas.
I. For practical scientific investigations into the sea fisheries, of which 2400 kr. form an honorarium for Hr. Lumholtz			7,200
II. Contribution to the Society for the Encouragement of Norwegian Fisheries			16,000
III. For inspection, &c., of cod-fisheries at Lofoten (1200 kr. only in the event of there being a congregation of fishermen at Raftsund) ...			31,950
IV. For increased police inspection at:—			
(1) Mackerel-fishery at Uleholmene	200		
(2) Spring cod-fishery at Namdal ...	1,000		
(3) ,, ,, Finmark ...	7,600		
(4) ,, ,, Söndmöre	3,200		
			12,000
V. For inspection, &c., at the herring-fishery in 1887			12,000
VI. For the encouragement of fresh-water fisheries:			
(1) To salary and office help for the inspector (400 kr. for personal expenses of present inspector)..	3,640		
(2) To two permanent assistants ...	3,400		
(3) To travelling expenses of the above officials in the fishing districts, and for travelling expenses of temporary assistants.	5,000		
(4) Inspection of salmon-fishery ...	7,600		
(5) For experimental transport of Wener salmon	200		
(6) For experimental marking of salmon and sea-trout	400		
(7) For encouragement of artificial spawning	1,000		
(8) Contribution:—			
a. For erection of salmon ladders at water-falls in accordance with plans given by the inspector in 1884 ... 1,667			
b. For erection of a salmon ladder at Haaelven in accordance, &c. 300			
	1,967		
			23,207
			102,357

[1] About 18 kronas = £1 sterling.

B. *Income.*

Salvage of nets and apparatus at Lofoten 600

In Sweden there is, strictly speaking, no Central Government Office for the fisheries. The fishery laws, and other special measures relating to the fisheries, are decreed by the Governors of the provinces or by the Department of the Interior. Previously, however, to the promulgation of any new law, the Governor must, pursuant to the Royal Ordinance of November 7, 1867, consult the Intendant of the Fisheries, who, conjointly with two assistants and one Instructor in Fish-breeding, are the public functionaries in connection with the fisheries in this country. Before the appointment of these officials, in 1864, there was (from the year 1855) a special Fishery Overseer (*Fiskeritillsyningsman*), or Inspector of the Sea Fisheries, in the province of Gothenburg and Bohus. He receives a salary from the Agricultural Society of that province, with subvention from the Crown, and is subordinate to the Governor of the province. The Intendant of the Fisheries and his assistants are under the control of the Royal Academy of Agriculture in Stockholm.[1]

The duties of the Intendant of the Fisheries are:—

(1) To investigate, with the aid of his assistants, the fisheries of the country.

(2) To propose or examine drafts of fishery laws or other measures for the improvement of the fisheries.

(3) To assist proprietors of fisheries with advice for hatching fishes, or with other measures for a rational management of the fisheries.

(4) To prepare and elaborate the fishery statistics.

(5) To control and direct the labours of the assistants and the fishery overseers.

Persons desiring the assistance of the fishery officials have to lodge intimation with the Royal Academy of Agriculture, and then the Intendant submits to the Academy a plan for the labours and the journeys of the fishery officials for the ensuing year. A fixed sum of 3500 kr. (about £198, or £83 for the Intendant and £55 for each assistant) is assigned for the travelling expenses of the fishery officials. Those requesting assistance have to pay 6*s.* per day.

The Intendant has to present annually a brief report on the labours of the fishery officials, and from time to time more detailed notices of the fisheries of the country. The Inspector of the Sea Fisheries of Gothenburg and Bohus submits an annual report on those fisheries to the Agricultural Society of the province.

The legal proceedings relating to the fisheries are briefly as follow:—If one or more proprietors of fisheries desire new or modified laws for the fisheries in their waters, or the Intendant of the Fisheries proposes such, the matter is submitted to the Governor of the province. The Governor then convokes all persons interested to meet and discuss the question. If the Governor, after having consulted the Intendant of the Fisheries, judges the proposals of the majority of the fishery proprietors suitable for the improvement of the fishery, those proposals are sanctioned, either as they stand, or with the necessary modifications. Anyone who dissents from the judgment may appeal to the Department of the Interior.

[1] The allowances of these officials from the Treasury are as follow:—Intendant, £250; two assistants, respectively, £111 and £83.

Germany, likewise, has no special central or chief authority for the management of the fisheries. The Empire has no right of control or even of cognizance of the fisheries. The State, however, gives annually a small sum to the German Fisheries Union (Fresh-water Fisheries). The control and management of the fisheries is therefore a matter for the different States which form the Empire. All these (Prussia included) have Inspectors of Fisheries (*Oberfischmeister*) and master-fishers (*Fischmeister*), but their duty only relates to the fiscal interests of the States and the rigorous observance of the fishery laws. They also give directions to the fishermen concerning the use of new and suitable fishing apparatus.

The control of the fresh-water fisheries of Prussia is vested in the Minister for Agriculture, Woods, and Forests, but there is no special Board for Fisheries. The various questions are worked up by clerks as they arise, as also is the preparation of Bills for the Prussian Chambers. In like manner the provincial control, the district (*Regierung*) control, and the Kreiss or county control, are carried out respectively by the Oberpräsident, the Regierungs Präsident, and the Landrath.

The Deutsche Fisherei Verein, of which Herr von Behr is chairman, is an independent association. It receives occasionally money grants from the Prussian Minister from a fund voted by the Prussian Chambers, and a regular grant, amounting at present to £1500 a year, from the German Parliament, towards the encouragement of fish-breeding throughout Germany.

Prussia for a series of years has had at Kiel a Commission for scientific researches in the German seas. It consists of four members, viz. a zoologist, a botanist, a physiologist, and a physicist. The present members are Professors in the University of Kiel, and Prof. Möbius (zoologist) is chairman. This Commission is placed under the control of the Ministry of Agriculture, and from that body it receives annually a sum of 9600 marks (£480) for general and personal expenses. The Commission publishes meteorological observations, statistics of the fisheries on the Baltic stations, and reports on scientific researches.

Much valuable work has been accomplished by this Commission in regard to the life-histories and development of fishes and the pelagic animals of the Baltic. Amongst other recent suggestions is one regulating the saleable size of certain fishes in special localities, *e.g.* the salmon and salmon-trout being fixed at 19½ and 11 inches respectively, the flounder at 6 inches, and the plaice at 7.

The Fishery Board of the Netherlands (Collegie voor de Zeevisscherijen) is composed of fifteen members, one of whom is president, and a secretary, who is not actually a member. All are nominated by the Crown, and the president out of a leet of two drawn up by the Board itself. The president and secretary form a kind of standing Committee by whom the every-day business is managed. All important affairs, however, have to come before the meetings of the Board, of which there are at least two yearly, viz. one in summer and one in winter. Very often the meetings are more numerous.

The majority of the members must be free from any direct interest in the fishing trade or the fisheries industries. The minority may, on the contrary, represent such interests. Actually the minority is composed (1) of a specialist for the herring-fishery—a great shareholder and head of a large fishing firm; (2) a member for the line-fishing; (3) one for the oyster industries; (4) one for the salmon and fresh-water fisheries; (5) one for the herring and cod fisheries; and (6) one for the fisheries of the Zuyder Zee.

Further, there are on the Board one shipowner and shipbuilder; one naval officer; several lawyers, several local authorities; and two zoologists.[1]

The members receive no salary—only their travelling expenses. Whenever a question is laid before the Board either by Government or at its own invitation, the President selects a special committee of three or five members to study, discuss it, and to draw up a report, which is then circulated, and afterwards, if necessary, discussed and voted about. All questions concerning fishery legislation are thus brought before the Board, and generally settled according to its advice.

There is a yearly grant (dating back, however, only a few years) of about £250 for experiments on the fishing industries, fish-culture, &c. Another £1000 are yearly devoted to salmon-culture, this sum being disbursed to the most successful fish-culturists at the rate of 5*d*. for a salmon a year and a half old (smolt), and two-fifths of a penny for one a few months old (parr). If the number of parr offered exceeds the sum which is available after the full value has been paid for the smolts, the culturists must either acquiesce in a reduction of price or keep their fishes. One or more members of the Board are always present when the fishes are set free into the rivers.

Since 1881 certain legal restrictions have been made with regard to the fisheries of the Zuyder Zee, and a staff of police organized on the inland sea, the chief officer being directly under the orders of the President of the Board. The same is the case with the police on part of the oyster territories. Those in Zealand have been, since the fresh start in 1870, under a special local Board.

In Italy the affairs relating to the fisheries are managed by the Minister of Agriculture, &c. The Minister nominates a Central Committee of twenty-four members. These consist of scientific men, magistrates, persons industrially interested in the fisheries, and some members of the Legislature (M.P.'s). Twelve members are elected or reappointed every year. The meetings of this Committee do not take place at certain fixed periods, but only by invitation of the Minister, who submits to the Committee the material to be discussed.

Besides the Central Committee there are a series of local Committees throughout the kingdom. These consist of the Captain of the Port, a zoologist, and technically experienced men. Their term of office lasts for three years from the date of appointment. The Regulation is published in the *Annali dell' Industria*, 1882, by the Ministry of Agriculture, Direzione dell' Industria e Commercio.

The duties of these local Committees are as follow:—

(1) To study and to propose all new regulations rendered necessary by experience.

(2) To collect the material for annual statistics.

(3) To give, on the demand of the Government, the Provinces, and the Communes, their opinion on matters directly or indirectly connected with the fisheries.

(4) To further the diffusion of the best methods of fishing and the advancement of the industries connected with them.

(5) To "render popular" the knowledge regarding the production, food, and diffusion of fishes and other useful marine animals.

From a consideration of the foregoing remarks on the Commissions, Boards, or Departments of foreign countries, it would appear that a central authority composed of a single individual, as in America, has certain disadvantages which can only be overcome by a rare combination of scientific eminence, administrative skill, and unbiassed judgment. It has, moreover, been a costly experiment; and it cannot be said that the Americans—even in the case of the cod—have succeeded so well as Dannevig at Arendal, in Norway, with the moderate resources at his disposal. It cannot be questioned, however, that the liberality of the Government of the United States has greatly aided scientific inquiry into marine life in general. Moreover, their efforts to increase the fresh-water fishes are most praiseworthy, and indeed in this they give us a good example, for there are still many fresh-water streams and lochs that would be of great value to the country if scientific fish-culture were put on a proper footing. The instance of the Outer Hebrides, *e.g.* North Uist, is sufficient in our own country. From the top of the Lee Hills the eye rests on a multitude of lochs—fresh-water and salt—which seem to be almost as extensive in superficial area as the shreds of land between them. In many of these, trout, salmon-trout, and salmon are found, so that one familiar with the agricultural poverty of these regions would not hesitate to place the culture of the water far before that of the land in regard to remuneration. A well-organized system of pisciculture in connection with these lochs would effect a revolution in the financial affairs of the people, and greatly supplement the food-supply for the community.

The French system does not seem to offer any suggestion of note in regard to the administration of the marine fisheries. The early labours of M. Coste and others in the culture of trout and salmon have, however, been of great service both to the adjoining Continental States, to us, and to America. It must not be forgotten also that M. Coste was one of those who took much interest in the Stormontfield experimental station on the Tay,

[1] This account does not quite correspond with the view published by the Fishery Board in their Sixth Annual Report, Part III., p. 305, for it is there stated that in Holland "There is a State Commission for Sea Fisheries, chiefly composed of naturalists and scientific men."

and personally, along with Mr. R. Buist, aided its establishment under the Committee of Proprietors.

Much that is useful for the purposes of administration may be learned from Norway, especially in connection with the Society for the Advancement of Norwegian Fisheries in Bergen, a place so classic to marine zoologists, from the days of Michael Sars to those of Fridtjof Nansen. Nowhere in Scotland can we point to a series of open-air reservoirs of pure sea-water, such as at Arendal, in which larval fishes can be raised to post-larval and subsequent stages; though at Stonehaven an enclosure of this kind formerly existed, and was used about thirty years ago in experimenting with young salmon (smolts). Yet no place is better fitted—both scientifically and economically—for such an arrangement than St. Andrews, as has indeed been often pointed out. The Norwegians are also fortunate in having the services of an able and original naturalist—trained from boyhood in marine zoology, besides others of European reputation. Sweden, though rich in names well known wherever zoology is studied, *e.g.* Lovén, places the direction of the fisheries under the Academy of Agriculture, the Governors of the provinces, and the Intendant; while the Inspector of the Sea-fisheries of Gothenburg and Bohus submits a special report to the Academy. The arrangements seem to work fairly, but it is doubtful if any feature of the system would be of advantage to this country.

No central authority for the whole of Germany yet exists, each of the States having Inspectors of Fisheries. Prussia, however, has the Special Commission at Kiel, the scientific work of this body being very much in its own hands. It has done good service in regard to the scientific aspects of the marine fisheries. The encouragement held out by the Deutsche Fisherei Verein to fresh-water fisheries is noteworthy and commendable.

One of the most satisfactory arrangements is seen in the Fishery Board of the Netherlands, in the composition of which all interests have been consulted. Moreover, the recent appointment of a scientific Superintendent of the Fisheries (viz. Dr. P. Hoek, an able zoologist) is important. The names of Hubrecht and Hoffman, who represent scientific zoology on the Board, are a sufficient guarantee that both tact and talent are at the service of the State. The solid scientific work done in the department by Profs. Hubrecht and Hoffman would alone give the Dutch Board a reputation, and when we add the names of other workers who have aided it, the position is considerably enhanced. Further, the mode by which scientific questions are referred to special committees—say of zoologists or physicists—and their reports thereon dispassionately discussed at meetings of the whole Board, obviates the possibility of the mistakes caused by a committee having perhaps only a single head to direct it in a particular inquiry.

The Italian system is satisfactory so far as the composition of the Board goes, though it seems to be a large one for efficiency, and the somewhat irregular nature of the meetings would hardly suit the methodical system generally followed in this country. The short period of office (three years), is perhaps not of much moment if re-election of the right men takes place. The fine Zoological Station at Naples under Dr. Dohrn (who, however, is too closely occupied to serve on the Central Committee of the Fisheries), gives the Italian Government a source of independent and reliable information, and of a different kind from that derived from the servants of a Board. The establishment of hatching stations, and the series of local committees throughout the country are features worthy of note, especially if due care be taken in the composition of the latter, so as to avoid the entrance of those who trade, it may be, on the credulity or ignorance of the fishing population. W. C. McIntosh.

SCIENTIFIC SERIALS.

L'Anthropologie, paraissant tous les deux mois, tome i. No. 1, 1890 (Paris).—The first number of the new French review of anthropology, formed by the amalgamation of the older *Revue d'Anthropologie* and the *Revue d'Ethnographie*, begins with an article by Dr. Topinard, one of its joint editors, on the skull of Charlotte Corday, which ranked among the most interesting of the curious contents of the anthropological section of the Paris Exhibition, to which it was presented by Prince Roland Bonaparte. The author explains that, in making choice of this special skull, his object is not to compare its craniological characteristics with the moral disposition historically attributed to the individual to whom it had belonged, but simply to make it the text for an exposition, which might serve our own and future students as a lesson for the examination and description of an isolated skull after the precise methods taught by Broca, and having regard to the present condition of our science. In accordance with this object, Dr. Topinard, confining himself almost entirely to craniometrical determinations, of which he gives a most comprehensive series, together with several well-drawn illustrations, only occasionally enters into the comparative relations presented by this cranium to other isolated crania. From this exhaustive lesson in craniometry it would appear that the skull of Charlotte Corday closely accords with the typical form of the female skull, established by Broca as characteristic of Parisian women, deviating only from the normally perfect feminine cranial type in presenting a certain flatness of the frontal region, and some traces of jugular apophysis.—The Bronze Age in Egypt, by M. Montelius. The author, in opposition to the opinions of Lepsius and Maspéro, believes that the use of iron was not known in the valley of the Nile as early as bronze, which was probably fabricated 6000 B.C., and that the use of the former metal was not sufficiently common to justify us in speaking of an Iron Age in Egypt before 2000 B.C. He, moreover, believes that we must consider the era of Egyptian civilization as belonging mainly to the Bronze Age.—A short notice of the works of Alexander Brunias, by Dr. E. T. Hamy.—On the rock-sepulchre of Vaphio, in the Morea, by M. S. Reinach. The exploration of this tumulus was undertaken last year at the cost of the Archæological Society of Athens under the direction of M. Tsountas, and although the contents have not yet been fully examined, there can be no doubt of their extreme importance to archæology, as it has been proved beyond question that this rock-sepulchre had remained intact till the present time. It appears from the report of M. Tsountas that the poniards and other implements, together with many of the numerous funereal objects brought to light by the explorations at Vaphio, are similar to the remains obtained at Mycenæ. Among these finds special interest attaches to two golden goblets carved in strong relief, representing both clothed, and almost nude, figures, engaged in the hunting and taming of wild bulls. M. Reinach proposes in a future number of this journal to discuss the Vaphio tumulus more fully, but in the meanwhile he appeals to English archæologists to test the accuracy of a statement published in 1813 by the German traveller Baron von Stackelberg, that the so-called Treasury of Atreus at Mycenæ had a few years earlier been ransacked by Veli Pasha, who was said to have disposed of part of its treasures to Lord North. Dr. Schliemann questions the truth of this report, but M. Reinach is of opinion that it bears evidence of authenticity, deserving the notice of Englishmen, and he hopes, in the interests of archæological science, that some of these precious objects may yet be found in one or other of the great English collections.—We may remark, in conclusion, that the present review surpasses its predecessors in the excellence of its printing and its illustrations, while it has the great advantage of being edited by MM. Cartailhac, Hamy, and Topinard. In the space allotted to the consideration of the scientific literature of various countries, to which more than half the entire volume is devoted, there are various notices of Russian, Hungarian, and other works, not generally accessible to the ordinary reader; but we trust that in future numbers the reports of English works and memoirs will not, as in the present number, be drawn exclusively from the Quarterly Journal of the Royal Geographical Society of London.

American Journal of Science, March 1890.—Sedgwick and Murchison: Cambrian and Silurian, by Prof. James D. Dana. The relations of these two geologists to one another, and to Cambrian and Silurian geology is given. The full paper appeared in NATURE of March 6 (p. 421).—Notes on the Cretaceous of the British Columbian regions; the Nanaimo group, by George M. Dawson.—Celestite from Mineral County, West Virginia, by George H. Williams. A large number of celestite crystals, from an extensive railroad cutting into a bluff of lower Helderberg limestone, has been investigated.—A method for the determination of iodine in haloid salts, by F. A. Gooch and P. E. Browning.—On the mineral locality at Branchville, Connecticut, fifth paper, by George J. Brush and Edward S. Dana; with analyses of several manganesian phosphates, by Horace L. Wells. A new member of the triphylite group—a sodium-manganese phosphate, which has been called natrophilite—has been found, and the rare mineral hureaulite identified in the Branchville minerals.—A simple interference experiment, by Albert A. Michelson. Two pieces of plane glass, silvered on

the front surfaces, are fixed against a block of wood, so that the angle between the two surfaces is slightly less than 90°. This simple apparatus will give the interference phenomena produced by means of Fresnel's mirror or bi-prism.—An improved wave apparatus, by John T. Stoddard. This is a method of demonstrating to a class the formation of the compound curves representing the combination of two simple sound waves.—On a recent rock-flexure, by Frank Cramer.—On the origin of the rock-pressure of the natural gas of the Trenton limestone of Ohio and Indiana, by Edward Orton. By the rock-pressure of gas is meant the pressure in a well which is locked in so that no gas can escape; and the author concludes that the rock-pressure of the gas of the Trenton limestone is due to the pressure of a water column under which it is held in the arches of the rocks. This explanation seems applicable to all gas fields.

THE *American Meteorological Journal* for January contains a continuation of Faye's theory of storms, and of Ferrel's convectional theory of tornadoes, both of which have been already referred to; the latter paper is concluded in the number for February. Of the other articles in these two months the principal are:—The mathematical elements in the estimation of the Signal Service Reports, by W. S. Nichols. He points out that attempts to measure the accuracy of the daily weather forecasts are liable to give rise to a confusion of ideas, and, confining his attention to rainfall, he lays down certain rules for testing the value of the predictions to the community when judged from the stand-points of quantity and quality, as well as the accuracy of the information.—On the use of the "sling" thermometer in the prediction of frosts, by Prof. H. A. Hazen. With the view of protecting delicate plants from destruction by frost, the author advocates the determination of the dew-point in the evening, and if it is found to be as low as 25°, and the air-temperature at 45° or lower, with a clear sky, frost may be expected, and the plants should be protected by smoke from burning straw, before the early morning.—On globular lightning, by Dr. T. C. Mendenhall. The author quotes many interesting instances of this rare phenomenon, the earliest case recorded being at Stralsund in June 1670; and he describes several instances in which it has been observed at sea. Photographs of the phenomenon are much wanted.—Diminution of temperature with height, by Prof. H. A. Hazen. He has recently spent several weeks on the summit of Mount Washington (6300 feet above sea-level), and finds that the diurnal range of temperature, which is very small, is not due to the heating of the air by the sun, but only to the convection currents caused by the warm rocks. The object of the paper is to endeavour to throw light on the true explanation of storm phenomena.—An interesting summary, by A. L. Rotch, of the Meteorological Conference held at Paris in September last, in connection with the International Exhibition. This is the first general account which has appeared in English.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 6.—"On the Development of the Ciliary or Motor Oculi Ganglion." By J. C. Ewart, M.D. Communicated by Prof. M. Foster, Sec. R.S.

The most conflicting views have for some time been held as to the origin, relations, and homology of the ciliary (motor oculi, ophthalmic, or lenticular) ganglion. By Remak, Schwalbe, Marshall, and others, the ganglion of the ophthalmicus profundus has been described as the ciliary ganglion, and this ganglion has frequently been regarded as the ganglion of the motor oculi nerve, and hence as homologous with the Gasserian and other cranial ganglia. The ciliary ganglion having been shown by van Wijhe to be quite distinct from the ganglion of the ophthalmicus profundus, the old view of Arnold has been recently revived, and already van Wijhe, Hoffmann, Onodi, Dohrn, and Beard have indicated that they regard the ciliary as a sympathetic ganglion. Hoffmann bases his belief on certain observations on the development of the ciliary ganglion in reptiles, while Onodi has adopted this view chiefly because in the higher vertebrates the ciliary ganglion receives a communicating branch from the sympathetic. But Beard, while considering the ciliary a sympathetic ganglion, states that in sharks he has seen nothing in support of "the mode of origin for the ciliary ganglion described by Hoffmann," in reptiles.

In studying the ciliary ganglion in Elasmobranchs I have been specially struck with its tendency to vary not only in the same genus or species, but in the same individual. Of the numerous specimens examined, I have only once found the ganglion entirely absent (in an adult *Raia radiata*), while I have occasionally (in *Acanthias*) found two well-developed ganglia on each side. Usually in sharks I found the ganglion lying in connection with the inferior branch of the motor oculi, while in skates it was generally in contact with the ophthalmicus profundus, or lying midway between the motor oculi and the ganglion of the profundus. In form the ganglion varies extremely, rounded or conical in some cases, in others it was represented by two or three groups of cells lying parallel to or in contact with the motor oculi.

In some cases ganglionic cells had wandered from the ganglion a considerable distance along the ciliary nerves towards the eyeball.

Although in sharks the ciliary ganglion often lay in close contact with the motor oculi nerve, no ganglionic cells were ever found either in the trunk of that nerve or on any of its branches. In skates the ganglion was usually more intimately related with the ophthalmicus profundus than the oculo-motor. In all cases the ciliary ganglion had at least two roots, one from the motor oculi, and one or two from the ophthalmicus profundus. In skates the profundus root always proceeded directly from the profundus ganglion, and the profundus ganglion was frequently found to be connected by a communicating branch with the Gasserian ganglion.

Both in sharks and skates, in addition to the ciliary nerves from the ciliary ganglion there were ciliary nerves proceeding from the ganglion and from the trunk of the profundus, and in some cases large ganglionic cells had wandered from the profundus ganglion along the ciliary nerves; occasionally a few large cells had migrated some distance along the main trunk of the profundus. In all cases the majority of the cells of the ciliary ganglion were only about half the size of the cells of the profundus ganglion.

In skate embryos under two inches in length no indication of the ciliary ganglion was discovered, and in shark embryos about ten inches in length the ganglion was frequently represented by small groups of cells in the vicinity of the inferior branch of the oculo-motor nerve. In sharks the first steps in the development of the ganglion were not observed, but in skates it was possible to make out all the stages. The first indication of the ganglion was in the form of a slender outgrowth from the inferior border of the large ophthalmicus profundus ganglion, which met and blended with fibres from the descending branch of the motor oculi. The *outgrowth from the profundus ganglion* was crowded with cells; the *fibres from the motor oculi*, like its root and trunk, were absolutely destitute of cells. At a somewhat later stage the cells had accumulated at the junction of the outgrowth from the profundus ganglion with the fibres from the motor oculi. It looked as if the blending of the two sets of fibres had formed a network which resisted the further migration of the ganglionic cells. In typical cases, at a still later stage, all the ganglionic cells had left the outgrowth from the profundus ganglion to form a rounded mass from which the ciliary nerves took their origin. In some cases some of the fibres which connected the profundus ganglion with the Gasserian seemed to reach and end in the ciliary ganglion. It thus appears that the ciliary ganglion stands in the same relation to one of the cranial nerves (the ophthalmicus profundus) as the sympathetic ganglia of the trunk stand to the spinal nerves, and that the ciliary ganglion may henceforth be considered a sympathetic ganglion. Further investigations may show that the ganglia in connection with the branches of the trigeminus (fifth) nerve may also be considered as belonging to the sympathetic system. In conclusion, I may say that I have found the vestiges of the ophthalmicus profundus ganglion in a five-months human embryo lying under cover of the inner portion of the Gasserian ganglion, and satisfied myself that the ophthalmicus profundus of the Elasmobranch is represented in man, as suggested by several writers, by the so-called nasal branch of the ophthalmic division of the fifth. To as far as possible clear up the confusion that has arisen from mistaking the ophthalmicus profundus nerve for a branch of the oculo-motor or of the trigeminus nerve, and the ganglion of the ophthalmicus profundus for the ciliary ganglion, it might be well in future to speak of the profundus as the *oculo-nasal* nerve and its ganglion as the *oculo-nasal* ganglion.

Chemical Society, February 20.—Dr. W. J. Russell, F.R.S., in the chair.—The following papers were read:—The behaviour of the more stable oxides at high temperatures, by Dr. G. H. Bailey and Mr. W. B. Hopkins. Previous experimenters have found that cuprous oxide is obtained when cupric oxide is heated to redness. The authors find that at higher temperatures a further quantity of oxygen is given off, and an oxide having the composition Cu_3O is formed. This is insoluble in mineral acids and even in aqua-regia, but can be converted into a soluble form on fusion with caustic potash, from which it separates on treatment with water. The oxides of lead and tin seem to behave similarly at high temperatures.—The influence of different oxides on the decomposition of potassium chlorate, by Messrs. G. J. Fowler and J. Grant. The authors have systematically examined the influence of the chief metallic oxides and certain unstable salts on the decomposition of potassium chlorate by heat, and the chief results obtained may be summarized as follows:—(1) Acid oxides, such as V_2O_5, WO_3, and V_3O_8, cause the evolution of oxygen at a much reduced temperature with the formation of a metavanadate, tungstate, or uranate. Chlorine is evolved in large quantity in these cases, but the whole of the oxygen of the chlorate is not liberated, since the compound of K_2O with the oxide is not decomposed by heat or by chlorine—

$$4KClO_3 + 2V_2O_5 = 2K_2O, V_2O_5 + 2Cl_2 + 5O_2.$$

(2) Alumina acts similarly but less energetically. (3) Chromium sesquioxide causes the evolution of oxygen at a lower temperature, chlorine also being liberated—

$$8KClO_3 + 2Cr_2O_3 = 4KCrO_4 + 4Cl_2 + 7O_2.$$

(4) The sesquioxides of iron, cobalt and nickel, cupric oxide, and manganese dioxide cause the evolution of oxygen at a comparatively low temperature accompanied by only a small percentage of chlorine; the oxide is left but little altered at the end of the experiment. The authors find that their results are in harmony with the theory of the action of manganese dioxide advanced by McLeod (Chem. Soc. Trans., 1889, 184). (5) The monoxides of barium, calcium, and lead cause no evolution of oxygen when heated with potassium chlorate, but the latter breaks up below its normal temperature with the formation of potassium chloride and a peroxide. (6) In the presence of such oxides as silver oxide and the peroxides of barium and lead, potassium chlorate acts as a reducing agent. No oxygen is liberated, but a perchlorate is formed. (7) Oxides such as those of zinc and magnesium are completely inactive. The authors find that the physical condition of the oxide is of importance, thus copper oxide prepared in the dry way is almost inactive; and further, that certain substances, as powdered glass, sand, and kaolin, assist the decomposition, although apparently they undergo no chemical change.—The interaction of hypochlorites and ammonium salts; ammonium hypochlorite, by Messrs. C. F. Cross and E. J. Bevan. The authors bring forward evidence of the formation and existence of ammonium hypochlorite in solution, but have failed to isolate the compound when produced by the action of an ammonium salt on a dilute solution of bleaching powder, or by the electrolysis of ammonium chloride solutions. It exhibits curious anomalies in oxidizing properties in comparison with other hypochlorites. It is without action on many colouring matters—for example, those of the vegetable fibre; it does not decolorize a solution of indigo in sulphuric acid, although it at once liberates iodine from potassium iodide, and it does not peroxidize hydrated lead oxide. On the other hand, it oxidizes sulphites and arsenites, and its effect on aniline salts is identical with that of ordinary hypochlorites. In the discussion which followed the reading of the paper, Prof. Armstrong suggested that probably the authors were dealing with a chlorinated derivative of ammonia, *e.g.* NH_2Cl; such compounds, according to Gattermann's experiments, being more stable than is usually supposed.—The action of phosphoric anhydride on stearic acid, by Dr. F. S. Kipping. One of the products of the reaction is stearone, $(C_{17}H_{35})_2CO$, and the yield appears to be as good or better than that obtained when salts of stearic acid are submitted to dry distillation.—Semithiocarbazides, by Prof. A. E. Dixon.—Note on the production of ozone by flames, by Mr. J. T. Cundall. Ilosva (*Ber. der deut. chem. Gesellsch.*, Referate 1889, 791) states that when all the products of combustion of various kinds of flames are collected, they do not exhibit the smell or taste of ozone. This is confirmed by the results of some unpublished experiments made by the author in 1886, but recently he has found that the air aspirated through a tube, 3 mm. in bore, whose mouth is fixed about 5 mm. above the tube, and 5 mm. away from the flame of a Bunsen burner, both tastes and smells strongly of ozone. Similar results were obtained both with luminous and hydrogen flames. It was not found possible to confirm this fact by any other test for ozone, owing to the impossibility of finding any sufficiently sensitive reaction which was not common to dilute nitrogen oxides. The author agrees with Ilosva that the smell and taste of ozone are the only trustworthy tests for it when it is present in small quantities, and that Houzeau's papers (impregnated with red litmus and potassium iodide), which at first sight should give the necessary distinction, since an acid gas would not be expected to give an alkaline product, are useless, inasmuch as nitrogen oxides also turn them blue.

Geological Society, February 26.—Mr. J. W. Hulke, F.R.S., Vice-President, in the chair.—The following communication was read:—On the relation of the Westleton Beds or "Pebbly Sands" of Suffolk to those of Norfolk, and on their extension inland, with some observations on the period of the final elevation and denudation of the Weald and of the Thames Valley; Part 3, on a Southern Drift in the valley of the Thames, with observations on the final elevation and initial sub-aërial denudation of the Weald, and on the genesis of the Thames, by Prof. Joseph Prestwich, F.R.S. In this third part of his paper the author gave a description of the characters of the Southern Drift, showing how it differs from the Westleton Beds in the nature of its included pebbles, which consist of flints from the Chalk with a large proportion of *chert* and *ragstone* from the Lower Greensand, while there is a total absence of the Triassic pebbles and Jurassic *débris* characterizing the Northern Drift. He traced the drift through Kent, Surrey, Berkshire, and Hampshire, and described its mode of occurrence. Another pre-glacial gravel was then discussed under the title of the Brentwood group, and its age was admitted to be doubtful. The author then entered into an inquiry as to the early physiographical conditions of the Wealden area, and gave reasons for supposing that a hill-range of some importance was formed in the Pliocene period after the deposition of the Diestian beds. From the denudation of this ridge, he supposes that the material was furnished for the formation of the Southern Drift, which may have been deposited partly as detrital fans at the northern base of the range. The relation of the Southern Drift to the Westleton Shingle and other pre-glacial gravels was considered, and the Westleton Beds were referred to a period subsequent to that of the formation of the Southern Drift. The influence of the meeting of the earlier Wealden axis with that of the folding which produced the escarpments of central England was discussed, and it was suggested that the result would be the genesis of the Thames valley and river. The following summary gives the results of the author's inquiry as developed in the other parts of the paper. He holds:—(1) That the Westleton Shingle ranges from Suffolk to Oxfordshire and Berkshire, rising gradually from sea-level to 600 feet. (2) That the lower Tertiary strata were co-extensive with this shingle. (3) That the upraising of the Westleton sea-floor, with its shingle, preceded the advance of the Glacial deposits, and that the latter become discordant to the former when traced westward, occupying valleys formed after the rise of the Westleton Beds. (4) That the Tertiary strata and Westleton Beds on the north border of the Chalk basin were continuous until the insetting of the Glacial period, when they were broken through by denuding agencies. (5) That none of the present valleys on the north of the Thames Tertiary basin date back beyond the Pre-glacial period. (6) That the same date may be assigned to the Chalk and probably to the Oolite escarpments. (7) That in the Thames basin, besides the Northern Drift, there is a Southern Drift derived from the Lower Greensand of the Wealden area, and from the Chalk and Tertiary strata formerly extending partly over it. (8) That during the Diestian period the Weald was probably partly or wholly submerged, and that between this and the insetting of the Glacial period, the Wealden area and the Boulonnais underwent upheaval resulting in the formation of an anticlinal range from 2000 to 3000 feet high. (9) That from the slopes of this range the materials of the Southern Drift were derived, and spread over what is now the south side of the Thames basin. (10) That this denudation commenced at the time of the Red Crag, and went on uninterruptedly through successive geological stages. (11) That consequently, though the Southern Drift preceded the Westleton Shingle, the two must at one time have proceeded synchronously. (12) That the valley-system of the Wealden area dates from Pliocene times—

the initial direction of the transverse valleys from pre-Glacial times—and of the longitudinal valleys from Glacial times. (13) That the Thames basin results from the elevation of the Weald and the flexures of the Chalk and Oolites of the Midland counties, and dates from a period subsequent to the Westleton Beds. (14) That the genesis of the Lower Thames similarly dates from early Pleistocene times, whilst its connection with its upper tributaries and the Isis, which possibly flowed previously north-eastward, took place at a rather later period. After the reading of the paper there was a discussion, in which the Chairman, Mr. Whitaker, Dr. Irving, Mr. Topley, Dr. Evans, and the author, took part. Dr. Evans congratulated the Society and Prof. Prestwich on his having been able to sum up the results of the observations of so many years in the series of papers which he had lately read.

Entomological Society, March 5.—Captain Henry J. Elwes, Vice-President, in the chair.—Mr. C. G. Barrett exhibited a number of specimens of *Dianthecia carpophaga*, Bork., bred by Mr. W. F. H. Blandford from larvæ collected near Tenby on flowers of *Silene maritima.* He remarked that the series included a number of forms intermediate between *D. carpophaga* and *D. capsophila*, and establish the fact that the latter is only a local variety of the former. Mr. W. H. B. Fletcher, Mr. Blandford, and Mr. McLachlan took part in a discussion as to the identity of the supposed species.—Mr. Barrett further exhibited a specimen of *Dianthecia luteago*, var. *Barrettii*, Db., also bred by Mr. Blandford from a larva found at Tenby, and he remarked that the species had not previously been taken in England; also a long series of forms intermediate between *Catoptria scopoliana*, Hw., and its small variety *parvulana*, Wilk., collected by Mr. E. Bankes, Mr. Fletcher and Mr. Vine, in Sussex, the Isle of Wight, and Pembrokeshire; also a specimen of *Botys mutualis*, Zell.,—a species widely distributed in Asia and Africa,—taken by Mr. C. S. Gregson near Bolton, Lancashire.—Mr. H. Goss exhibited several abnormal specimens of *Arctia caja*, bred last December. The object of the exhibition was to show the effect produced by forcing the larvæ, and subjecting them to unusual conditions. It was stated that the peculiarity of the colour of the hind wings of the female parent had not been transmitted to any of the offspring.—Mr. Blandford referred to two specimens of a species of *Cardiophorus*, from Tenby, which he had exhibited at the August meeting of the Society as *Cardiophorus cinereus*, and stated that subsequent investigation had led him to hand them to Mr. Champion for determination. Mr. Champion was of opinion that they did not belong to the same species; that one of them was *C. asellus*, Er., and the other, probably, *C. equiseti*, Hbst., a species new to this country.—Mr. C. J. Gahan read a paper entitled "New Longicornia from Africa and Madagascar."—Captain Elwes read a paper entitled "On a new species of *Thymara* and other species allied to *Himantopterus fuscinervis*, Wesmael."—Dr. Sharp read a paper entitled "On some Water Beetles from Ceylon."—Mr. J. J. Walker communicated a paper entitled "Notes on Lepidoptera from the Region of the Straits of Gibraltar." Mr. F. Merrifield, Mr. B. G. Nevinson, Captain Elwes, and Mr. G. Lewis took part in the discussion which ensued.—It was announced that papers had also been received from Mr. E. Meyrick, Prof. Westwood, and Mynheer P. C. T. Snellen.

Royal Meteorological Society, March 19.—Mr. H. F. Blanford, F.R.S., Vice-President, in the chair.—The following papers were read:—A brief notice respecting photography in relation to meteorological work, by Mr. G. M. Whipple. The first person to use photography for obtaining meteorological records was Mr. T. B. Jordan, of Falmouth, in 1838. Some years later, Sir F. Ronalds and Mr. C. Brooke devised more complete and elaborate apparatus; the arrangement of the former being now in use at the Observatories of the Meteorological Office, and that of the latter at the Royal Observatory, Greenwich. Reference was also made to Mr. J. B. Jordan's form of sunshine recorder, and to Captain Abney's photo-nephograph. The various photographic processes which have been employed in connection with these instruments were fully described.—Application of photography to meteorological phenomena, by Mr. W. Marriott. The author showed how photography could be most usefully employed for the advancement of meteorological knowledge. Much valuable information had been recently obtained from photographs of lightning and clouds. An interesting collection of such photographs was shown on the screen, together with others illustrating floods, whirlwinds, tornadoes, hailstorms, frost, snow, &c.—After the reading of these papers, the meeting was adjourned to allow the Fellows to inspect the Exhibition of Instruments, &c., an account of which we print elsewhere.

Mathematical Society, March 13.—J. J. Walker, F.R.S. President, in the chair.—The following communications were made:—Perfect numbers, by Major P. A. MacMahon, R.A.—The relation of distortion in prismatic images to dispersion, by Dr. J. Larmor.—On the satellite of a line relatively to a cubic, by the President (Prof. Greenhill, F.R.S., V.P., in the chair).—An approximate relation connecting successive terms of the expansion for tan x, by G. Heppel.

PARIS.

Academy of Sciences, March 17.—M. Hermite in the chair.—M. Maurice Lévy communicated a paper on the application of electro-dynamical laws to planetary motions. In a communication of February 17, M. Tisserand applied Gauss's formula of electro-dynamical attraction to the movement of celestial bodies without at all asserting it to be true. M. Lévy concludes that the formula is contrary to the doctrine of energy and to the facts, and shows that Riemann gave a law which, like that of Weber, is in accord with both.—On the photographic halo, and a method of making it disappear, by M. A. Cornu. The author has investigated the appearance and cause of the halos which surround intense points of light on a photographic plate, and the conditions necessary to remove them.—Under agricultural chemistry, M. Berthelot discusses the facts relating to observations on the reactions between the soil and atmospheric ammonia.—M. P. Schutzenberger, in researches on some phenomena produced during the condensation of gases containing carbon under the influence of the silent discharge, has investigated the composition of the brown solid formed together with carbonic acid from the condensation of carbonic oxide. The experimental results give a formula intermediate between $C_{12}H_2O_{10}$ and $C_{12}H_2O_{11}$.—Method of determining the pole of an ellipsoid of three unequal axes by the observation of its catoptric images, by M. D. E. Sulzer.—On a new system of electrical accumulators and some accessory apparatus, note by M. Charles Pollak.—On the double thiosulphates of lead and sodium, by M. J. Fogh.—The action of sulphuric acid on aluminium, by M. A. Ditte. The author finds aluminium to behave much like amalgamated zinc. With a smooth plate of this metal immersed in dilute cold sulphuric acid for some time but little hydrogen is liberated owing to the formation of a protecting film of the free gas, and that any circumstances tending to facilitate the removal of this film increase the rapidity of action of the acid; for instance, a trace of a chloride of any metal reduced by aluminium causes the plate to be comparatively rapidly attacked owing to the roughening of the surface due to the deposition of a metallic film; again a similar effect is obtained when the reaction is caused to occur in a vacuum, because of the freer disengagement of hydrogen. The product of the reaction is in the first place neutral sulphate of aluminium, but the reaction continues further, a basic sulphate being produced with further evolution of hydrogen. The conclusion is drawn that aluminium acts normally, in accordance with the heat of formation of its salts, when in contact with sulphuric acid or metallic sulphates, and that the slowness of the reaction is due to the mechanical interference of the liberated hydrogen.—On a new crystalline form of ammonium chloride, by MM. G. Geisenheimer and F. Leteur. M. Le Bel has shown the possibility of a second form of ammonium chloride (*Comptes rendus*, January 20, 1890); the authors give data leading them to conclude that they have probably obtained the second form, rendered stable by the presence of a slight impurity.—Note by M. J. Meunier, on the mono- and di-benz-acetals of sorbite.—On the α dextro- and lævo-rotatory borneol camphorates, by M. A. Haller. The author draws the conclusions—(1) that the total etherification of camphoric acid is only effected at a relatively high temperature and with the anhydride; (2) that isomeric bodies are certainly produced under these conditions; (3) that camphoric acid, in the acid ethers studied in this note, is analogous to phenol in its reactions.—On oxytetric acid, by M. Ch. Cloez.—On the value of the heat of hydration of malic acid, by M. Iw. Ossipoff.—Note by M. J. A. Muller, on the dissociation of the hydrochlorides of amines and dissolved salts of fatty acids. Using phenolphthalein as indicator, the author has been enabled to trace the dissociation of

these bodies on diluting or heating their solutions.—A botanical note, by M. Léon Guignard, on the formation and differentiation of the sexual elements which take part in fertilization.—Another botanical paper, by M. A. Prunet, on the comparative structure of the nodes and internodes in the trunk of the Dicotyledones.—Under geology, M. de Folin has a paper on the formation of nummulitic rocks. He concludes that these rocks are formed by the work of an organism of the same order as the Rhisopodes.—Also under geology, M. Stanislas Meunier contributes some chemical researches on the fossil shells of Foraminifera, Mollusks, and Crustacea. He has investigated the composition of the flocculent organic residue formed when these fossil shells are dissolved in acid.—On Pyrenean kersanton, its age and affinities with ophite, by M. J. Caralp.

Berlin.

Physiological Society, February 28.—Dr. Rosenstein exhibited a patient with distension of the lymphatics in the leg, and fistulous openings which discharged an albuminous fluid sometimes amounting to 1100 c.c. in a day. Dr. J. Munk has made observations on this fluid. It is sometimes transparent, but is always milky after a meal containing fat. It thus resembles chyle rather than lymph, and probably really is chyle. At least two-thirds of the fat given at any one meal reappeared in the fluid from the fistula. On giving olive oil, fat appeared in the fluid in two hours, increased steadily till its maximum after five hours, then diminished, and in ten or twelve hours disappeared. With a harder fat, *e.g.* mutton fat, the phenomena were the same, but were longer in appearing. Erucic acid given to the patient appeared as a neutral fat, and not as free acid, synthesis having been effected in the body. No appreciable absorption of fat occurs from the rectum. Large doses of starch or sugar scarcely increased the percentage of sugar, nor did large meals of albumen increase that of proteids in the fluid. Thus the only food-stuff which leaves the intestine by the lacteals is fat.

Meteorological Society, March 4.—Dr. Vettin, President, in the chair.—Dr. Wagner spoke on fire-damp explosions in mines in their relationship to cosmic and meteorological conditions. He discussed the collection of the gas, the conditions necessary for its explosion, the part played by coal-dust, and the several chance circumstances which may lead to the non-discovery of the gas in the workings. He next discussed the various means available for avoiding and removing accumulations of fire-damp, and gave an account of researches on the relationship of its explosion to varying barometric pressures. His own work had consisted in working up the statistics of the Dortmund mining district in which explosions are more frequent than in any other state of Prussia. The reports cover a period of 21 years and give a record of 7000 explosions. He first compared the numerical relationship of the explosions with the phases of the moon, and concluded that there is no connection between the two. He then made a similar comparison of their frequency with the rotational period of the sun, taking the latter as 25·5 days: the result was again negative. He finally compared their frequency with periods of 27·9 days, this being, according to Buys-Ballot, the cycle of temperature variations resulting from the sun's rotation. In this case the curves he obtained were quite uniform and regular, showing a maximum on the third day and a second maximum on the twentieth. He refrained from drawing any definite conclusions from this last observation in view of the numberless chance circumstances which may lead to explosions.

Physical Society, March 7.—Prof. Kundt, President, in the chair.—Dr. Rubens spoke on the employment of the bolometer for observing the electrical radiations of Hertz as carried out by himself and Dr. Ritter. Up to the present it had not been found possible to measure the intensity of the radiation owing to the extraordinarily minute amplitude of the oscillations; but the speaker had been able to carry out the determination by means of a bolometer whose construction and working he fully described. It consists essentially of an accurately balanced primary Wheatstone bridge, two of whose arms are again converted into secondary Wheatstone bridges. If a current passes through one of them its resistance is altered by the rise of temperature, and the galvanometer gives a proportionate throw. A similar effect is produced by a wave of electrical radiation, and hence its amplitude can be measured by this bolometer when once it has been calibrated. When experimenting with the polarizing wire-grating it was found that there is a constant relationship between the intensity of the rays which pass the grating and the angle of inclination of the wires to the plane of oscillation of the rays. It was further observed that the energy which does not pass the grating is reflected, and to the extent of 98 per cent., when the wires are at right-angles to the plane of oscillation. Experiments in illustration of the above were shown at the end of the communication.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

THURSDAY, APRIL 3, 1890.

TECHNICAL EDUCATION IN THE CODE.

MR. KEKEWICH is to be congratulated on the reception which his Code has hitherto met with. From all sides it has been received with a unanimous chorus of congratulation, tempered only by the difficulty which has been experienced in distinguishing clearly what is new from what is old. Many parts of the Code have in fact been entirely re-cast and re-arranged, and in the absence of the schedule of alterations which it is customary to issue as an appendage to the Code, the compilers of abstracts for the daily papers have this year had a terrible time of it. They have been unable to criticise the alterations without reading the document through, and even this unwonted exercise has not prevented them in more than one case from reproducing as new, old and familiar articles, the order of which has been changed.

But these trials, and the further difficulty of picturing at once the effect on various classes of schools of the action and reaction of numberless modifications, additions, and omissions both small and great, fortunately affect us but little. A great part—some would say the most important part—of the alterations, deal with matters of finance, management, and control, rather than directly with the education given in the schools. And it is with this that we are chiefly concerned in the present article.

So far as regards the changes in curriculum there is no ambiguity. We may fairly congratulate the Government on a solid and unequivocal advance in the right direction. In fact, the framers of the Code have gone a very long way (without the aid of Sir Henry Roscoe's new Bill) to enable elementary school managers to provide technical education, or more strictly to provide the general educational basis on which all specialised technical instruction must be founded.

A few weeks ago, when dealing with the changes in the new Scotch Code, we ventured on two forecasts regarding the coming changes in English elementary schools. The first was that the English Education Office would be unable to maintain its previous *non possumus* attitude on the subject of manual instruction after the Scotch Department had virtually assented to Sir Horace Davey's now famous opinion by including manual training among the grant-earning subjects of the Code. The second was that the policy of the Department would be found to lean (as in Scotland) towards the encouragement and extension of "class subjects," taught throughout the whole school, even at the expense of "specific subjects" which only affect a small minority of picked scholars.

Both these forecasts, as we shall see, have been verified, but this does not by any means exhaust the new provisions by which the range of study, especially of technical and scientific instruction, is extended. We will consider some of the changes in order.

To take first the most striking change, the clause by which manual instruction for the first time is recognized as a part of elementary education will come to many as a surprise. It indicates a change of front on the part of the Department on a matter of interpretation of the Education Acts. Hitherto the authorities at Whitehall have declared that the recognition of manual training without a new Act of Parliament was impossible. They asserted that their hands were tied by statute. That was the position a few months ago. And now no statute has been altered, and manual instruction is in the Code. It may be taught either in or off the school premises, and either by the ordinary teachers of the school or by special instructors, provided "special and appropriate provision approved by the inspector is made for such instruction and the times for giving it are entered on the approved time-table." In a later clause manual instruction is specially recognised as an object to which part of the school funds may be devoted.

Thus the aim of the Bill just drafted by the Technical Association is virtually attained without it. One omission, however, may attract notice. No special grants are provided in aid of manual training. In Scotland, it becomes a "class subject," and is paid for accordingly, but no grant is attached to it in the English Code. We presume, however, that there is nothing to prevent it being paid for as a specific subject under the clauses which provide for grants in aid of any subject "if sanctioned by the Department," provided that "a graduated scheme for teaching it be submitted to, and approved by the inspector."[1]

There is, however, yet another way in which grants for manual instruction may be made, and, reading between the lines of the Code, it looks not unlikely that the Government mean to adopt it. Drawing is already paid for by the Science and Art Department, and in Art. 85 (*b*) of the new Code we find drawing and manual training coupled together. Boys in a school for older scholars must be taught drawing "with or without other manual training." Unless, then, the present confusion of overlapping authorities is to be made worse confounded, it is reasonable to expect that both these subjects will be under the same Department, and we shall look with interest for the inclusion of manual instruction in the next Science and Art Directory. There is this further inducement to the Government to take this course, that payments made by the Science and Art Department fall outside the 17*s*. 6*d*. limit. In any case, two main conditions should be fulfilled in making grants for manual instruction: first, that they should not be given on results of examination; secondly, that they should be dependent on a really effective inspection. The first condition is necessary because no satisfactory scheme of individual examination in such a subject can be devised so as to be a real test of efficiency; the second is necessary to guard the public purse from being depleted to enable small children to construct bad soap-boxes when they ought to be in school.

But if the official recognition of manual instruction (which we assume includes, as in the Technical Instruction Act, "modelling in wood, clay, and other material"), is the most striking victory of the advocates of technical instruction, there are other changes of greater importance from an educational point of view.

The Department has at last screwed itself up to the

[1] Arts. 16 and 101 (*f*).

point of refusing to acknowledge any boys' school as efficient which does not include drawing in its curriculum. This is an enormous advance—how great will be seen if we remember that less than a million out of the five million scholars of our elementary schools are receiving instruction in drawin; at the present time. It is a great advance, also, on the halting proposal of last year, when the requirement was restricted to large schools which aimed at the maximum grant. When a radical change, such as the present one, is proposed, it is only reasonable that the transition stage should be made easy for schools which have to adapt themselves to the new requirements. We make no complaint, therefore, of the year of grace granted before the regulation comes into force, nor even of the power given to the inspector to dispense with it altogether in cases where the "means of teaching drawing cannot be procured." This provision would, indeed, seriously cripple the usefulness of the change if it were intended to be permanent. But clearly it is only meant to obviate temporary hardships in small schools; and we may congratulate ourselves that within a short space of time, every boy (or at least every boy among the working classes) will be receiving instruction in what is stated by all authorities to be the indispensable basis of almost all technical instruction. As a corollary to the change, there is another of less importance, but of value in its way, which makes drawing an alternative to needlework for boys in infant schools.

While thus the manual instruction of boys is provided for, a useful extension is given to the curriculum for girls, by the provision of a grant for laundry work calculated on much the same principle as that for cookery.

Passing to science teaching, the reforms introduced are no less satisfactory. In the first place, science instruction (as well as manual training) is placed on the same footing as cookery as regards facilities for the grouping of schools for central instruction, and attendance at such centres will count as attendance at school.

A still more important change is the extension of the range of class subjects. Under former Codes a single course of elementary science was sketched out meagrely enough in Schedule II., while managers were invited if they pleased to submit alternative courses to the inspector. The result might have been expected. Science teaching gives in any case more trouble than geography, and the additional necessity of framing their own courses of instruction was quite enough to deter managers from taking up the subject. Now, however, while still giving permission to managers to draw up other courses of instruction, the Department gives a lead by suggesting as examples no fewer than eight different courses in various branches of science, which are embodied in a supplement to Schedule II. The subjects thus treated are mechanics, physiology, botany, agriculture, chemistry, sound, light, and heat, electricity and magnetism, and domestic economy; while the model course still retained in the main schedule embodies a scheme of elementary instruction in "nature knowledge" of a more mixed and varied character.

In each of the first two standards the instruction is to consist of thirty object-lessons in common things, designed to lead on to the more specialised instruction in the third and higher standards, the courses for which follow (perhaps somewhat too closely) the syllabus laid down for the corresponding subjects in the schedule of specific subjects. It has, of course, been necessary somewhat to simplify and curtail the schemes of instruction in adapting courses framed for picked pupils to suit the capacity of the whole school. It seems to us that the process of simplification might in some cases be carried still further with advantage. Elementary physics for children should consist of a general view of the properties of matter and the forces which act upon it, rather than a more detailed study of one out of many branches of the subject. This was the line taken up by Michael Faraday in his inimitable lectures to children on the "Physical Forces." This too is the view of the Scotch Department, which has laid down a course of class instruction in "Matter," designed to give general preliminary notions of the whole range of physics. And, we may add, this also is the view taken by the Science and Art Department in framing the alternative course in physics for those who (like the vast majority of elementary school children) are not likely to carry their study of physics to a higher stage.

This, however, is a matter of detail, while the suggestion of alternative courses in science, linked to the instruction of the Kindergarten by graduated object-lessons in the first two standards, is a reform which we cannot praise too highly.

Other changes to be noticed are the inclusion among class subjects of history, and the disappearance of the requirement that English grammar should be compulsory as a class subject.

Turning to the schedule of specific subjects, we find less alteration. Mensuration is separated from Euclid and the alternative course of mechanics disappears. There are a few slight changes in the syllabus of the various subjects. Thus the law of conservation of energy drops out of the course on mechanics, presumably because the idea is thought too hard for young children to grasp. But if it be too difficult for *picked* scholars in the fifth and higher standards, how comes it that in the new Scotch Code this very law appears in the syllabus for the "*class*" subject of "matter" (which we have alluded to above), as part of the course suitable for the whole of Standard IV.? Are Scotch children so very far in advance of English as this difference would seem to imply?

If, however, the fourth schedule presents few changes worthy of note, considerable additions are made to the list of specific subjects for which no special syllabus is suggested, such as book-keeping, shorthand, German, and (in Wales) Welsh. In this way the demand for commercial instruction is met, though how far advantage will be taken of the permission to present scholars in these new subjects remains to be seen. And lastly, payments will be made on account of any other spe ific subject which the Department may sanction, provided a raduated scheme of instruction be submitted to the inspector.

We have now completed the survey of the purely educational changes of the Code. Henceforth (assuming, as we do, that the provisions of the Code will come into force much in their present form) there can be little complaint on the part of advocates of scientific or t chnical instruction that its introduction into elementary schools is hindered by the action of the Department. There need be no longer any talk of an educational ladder

with its lower rungs wanting. How far managers will take advantage of their powers remain to be seen. The changes which are compulsory, such as that which makes drawing universal for boys' schools, will, of course, take effect widely at once. Those which are merely permissive may be slow in their operation. Meanwhile, those who are in earnest about the introduction of such subjects as manual training into elementary schools could not better occupy the time which intervenes before the new Code comes into force, at the end of August next, than in perfecting a graduated scheme of instruction such as may be confidently recommended to school managers to submit to the Education Department.

We have laid stress in this article on the proposed changes in the elementary school curriculum, because, important as these are, they are likely to be overshadowed in the coming discussions on the Code by other questions which appeal more directly to party politicians. We have thus left ourselves no room to do more than allude to other reforms which will affect as powerfully the educational character of our schools as the widening of the course of study. After all, the main guarantee of efficiency is the quality of the teaching staff. The new Code raises the requirements of the Department as to minimum staff, improves the regulations regarding the examination and training of pupil teachers, and provides for the creation (on a very limited scale it is true) of day Training Colleges attached to the Universities or Higher Local Colleges, as well as for the attendance of day students at the existing Training Colleges. The Code further revises the system under which the Parliamentary grant is paid, and almost entirely abolishes payment on results of individual examination. It gives freedom to teachers to classify their scholars as they please, so that a child may be in three different standards in the three R's, and in two different standards again in the two class subjects. All these and other changes, which demand much more notice than we can give them, make the Minute of the Department which has just seen the light emphatically a "Teachers' Code."

THE CAVE FAUNA OF NORTH AMERICA.

The Cave Fauna of North America, with Remarks on the Anatomy of the Brain and Origin of the Blind Species. By A. S. Packard. Pp. 1-156, with 27 Plates.

THIS important memoir is the first of vol. iv. of the "Memoirs of the National Academy of Sciences," and contains the results of an examination of the Mammoth Caves in Kentucky made during the months of April and May 1874, and of some other caves in Indiana and Virginia which were visited by the author at a later date.

A description of eighteen caves, with notes on their hydrography and geological age, and an account of the fauna of those which are better known, form the first section of the memoir. The caves form the natural drains of the country, all the surface drainage being at once carried down into them through the innumerable "sink-holes" which pierce the thin stratum overlying the Carboniferous Limestone, in which the caves are excavated. The Mammoth Cave is the largest and best known, with its 150 miles of passages and avenues, frequently crossing one another at different levels.

Their geological age is uncertain, but there is very little doubt but that they assumed their present proportions long after the melting of the glacial ice and are coæval with the Niagara river-gorge. And as the caves must have been incapable of supporting life while flooded, their preglacial fauna, if they had one, must have been killed off, and they could not have become ready for their present fauna until comparatively recent times; therefore, they must have been colonized by members of the existing fauna. The mode of colonization is very simple. Tracks of bears, wolves, and smaller animals occur in nearly all those caves which are easily accessible from without, and clinging to the skins of these animals various small Arthropods may have been carried in; other species of insects and Myriopods which naturally lead a subterranean life may voluntarily enter the fissures and sink-holes which abound in this region; others, again, get carried in by the agency of torrents which flow in during certain seasons of the year, as, for instance, the eyed fishes and species of Crustacea which abound in the surface waters.

That cave animals have entered the caves from without is further corroborated by the fact that in the case of very many cave species closely allied outdoor species are found in great numbers in the immediate vicinity of the caves. Also caves situated near one another are populated by a similar fauna, which allows us to classify them in groups closely corresponding to the various zoo-geographical regions of the country.

The author then proceeds to the systematic detailed description of the fauna, a section which constitutes more than one-third of the memoir. As in the case of the fauna of the outside world, the species of Arthropoda form a very large percentage of the total number of cave species; but, however different the groups to which the various species belong may be, they possess the common characteristics of slenderness of body and appendages and of the absence of functional eyes. The systematic description is followed by lists of all the North American and European cave species known at present, showing that the European species are by far the most numerous. It is therefore argued that the European caves have been inhabited for a longer period than the American.

Although the animal kingdom, at any rate as far as certain groups are concerned, is comparatively well represented, vegetable life is almost absent, evidently owing to the dryness and the absence of light; in fact, so far as is known at present, it is only represented by a few Fungi and two or three Moulds. The air must also be comparatively free from the germs of bacteria of putrefaction, as the decay of organic refuse is very slow, and meat hung up in the cave will keep a long time. But though bacteria are absent, their office is performed by larvæ of the blind beetle (*Adelops hirtus*) and of flies.

Cave animals are mostly carnivorous. The blind fish (*Amblyopsis*) lives on Crustacea, and especially on the blind crayfish, which in its turn preys upon living *Cæcidotea*, but how they and other small aquatic Crustaceans maintain an existence is unknown. The Myriopods, which are very common, feed on decayed wood and fungous growths.

However, in all cases, as a rule, food must be very

scanty, and "lack of food as well as the absence of light was one of the factors concerned in the diminution of size and in the slenderness of blind cave animals as compared with their lucicolous allies."

The effect of total darkness upon animals is twofold. Firstly, colour is either entirely or partially bleached, and, secondly, the sense of sight is lost. Eyesight may be lost in various ways. Either the optic lobes and nerves may atrophy, while the retina, pigment, and lens remain more or less persistent; or the optic lobes and nerves may persist, while the retina and eye-facets atrophy; or, again, the whole of the optic apparatus may atrophy. Examples of all these cases are given in the important chapter which is devoted to a description of the anatomy of the brain and eyes of certain blind Arthropods, and illustrated by numerous drawings of sections through various regions of the head.

It is argued that this atrophy must be comparatively sudden and wholesale, because no series of individuals has been found with the optic lobes or nerves in different stages of disappearance. Transitional forms have been observed with eyes with a varying number of crystalline lenses, as in the case of *Chthonius*; those individuals which live near the mouth of the cave have better developed eyes than those which live far in. And surely, on further examination, more transitional forms will be discovered, as animals must be continually getting into the caves from the outside; their descendants becoming gradually adapted for cave life, until they finally reach the degree of modification of the present older occupants.

As the sense of sight diminishes, it is compensated by an increase of the delicacy of other senses. The tactile and olfactory senses are rendered more sensitive, the appendages become much more slender, and the blind form is altogether more timid and cautious than its eyed allies, as has been particularly noticed in the blind crayfish.

The last part of this memoir deals with what is of most general interest to the biologist, viz. the bearing of these facts upon the theories of evolution. The author states that here the term "natural selection" expresses the result of a series of causes rather than any one cause in itself. The most important of these causes are: the *change of environment*, from light to partial or total darkness, involving diminution of food, the disuse and loss of certain organs, with compensation as has been mentioned above; *adaptation*, enabling the more plastic forms to survive and perpetuate the stock; *heredity*, which operates to secure the future permanence of the newly originated forms—the longer it acts, the earlier will the inherited characters appear in the development of the animal; and, lastly, *isolation*, which, after adaptation and heredity have established the typical characters, prevents intercrossing with out-door forms, and thus insures the permanence of these characters.

The author adduces facts which seem to prove that the organic adaptations to a life in darkness may have been induced after but a few generations, perhaps one or two only, resulting in the comparatively rapid evolution of cave species. If that be the case, then, there is no reason why they should not be produced artificially, but at present no experiments have been made to prove the mutual convertibility of cave species and their lucicolous allies. If a cave species could be made to revert to an epigean form by keeping it for a number of generations in a gradually increasing amount of light; and if, on the other hand, a lucicolous species could be changed into a cave form by a converse process, the theory of occasional rapid evolution due to sudden changes in the environment would receive its final proof.

Mr. Packard draws attention to the interesting parallel between the life of the abysses of oceans and lakes and that of caves. In both cases vegetable life is almost absent, and a large proportion of the animal forms have become similarly modified with regard to the degeneration of the optic organs and corresponding development of other organs as compensation. But while caves have only been populated comparatively recently, the ocean abysses have had inhabitants for a very much longer time, and consequently these have had time to become much more highly specialized than the inhabitants of caves.

This most valuable contribution terminates with a bibliography containing the titles of previous publications on the subject, and we must not omit to mention that in a separate chapter a list is given of the known non-cavernicolous blind animals. As far as the higher classes are concerned, this list contains about the same number of species as the one of the blind cave-dwelling forms.

R. T. G.

LINEAR DIFFERENTIAL EQUATIONS.

A Treatise on Linear Differential Equations. By Thomas Craig, Ph.D. Vol. I. Equations with Uniform Coefficients. (New York: John Wiley and Sons, 1889.)

TREATISES on this subject have been somewhat numerous of late. We recently noticed in these columns an excellent, but fairly elementary work, "On Ordinary and Partial Differential Equations," by Prof. Woolsey Johnson. The student who wishes to enter on the profitable perusal of the book before us must be well versed in all the ordinary modes of procedure,[1] and then he will find that Dr. Craig is well qualified to lead him through the intricate windings of this difficult branch of mathematics. The advanced student will find the author's analyses of use to him whilst reading the various original memoirs here introduced to him, for the first time, in English. Some may remember that Mr. Forsyth, in his classical treatise, omitted the investigations of Fuchs, the recent researches of Hermite and Halphen, contented himself with a slight sketch of Jacobi's method for partial differential equations, and did not at all touch upon the methods of Cauchy, Lie, and Mayer. The consideration of these matters he reserved for a future volume.

The theory of the subject before us, *i.e.* of linear differential equations, almost owes its origin, in Dr. Craig's opinion, to two memoirs by Fuchs, published in vols. lxvi. and lxviii. of *Crelle's Journal* (1866, 1868)

"Previous to this the only class of linear differential equations for which a general method of integration was known, was the class of equations with constant coefficients, including, of course, Legendre's well-known equation, which is immediately transformable into one with

[1] "The reader is of course supposed to be familiar with the ordinary elementary theory of differential equations" (p. 32).

constant coefficients. After the appearance of Fuchs's second memoir, many mathematicians, particularly in France and Germany, including Fuchs himself, took up the subject, which, though still in its infancy, now possesses a very large literature."

As happens in such cases, these memoirs have to be dug out of journals and publications of learned Societies before the student can be put in possession of results obtained. It is for this labour of research, and then for the arrangement in due sequence of theorems, that the reader has to thank Dr. Craig.[1] Even in the first two chapters, where most of the results are old, the treatment is comparatively new, being founded upon papers by Laguerre (*Comptes rendus*, 1879), and upon memoirs, or works, by Briot and Bouquet and Jordan; reference is also made, in connection with a proof by Jordan, to a paper by Picard (*Bulletin des Sciences Math.*, 1888). Here we may note that the author reserves an account of the investigations of Laguerre, Halphen, and others, from a still higher point of view, to a subsequent volume.

This first instalment discusses principally Fuchs's type of equations, but accounts are given of the researches of Frobenius (chapters iv., viii.), Markoff, Heun, Riemann, and Humbert (chapter vi.), Thomé (chapter ix.), Halphen (chapter xii.), Forsyth's canonical form and associate equations, Brioschi, Lagrange's adjoint equation, Halphen's adjoint quantics and Appell's theorem (chapter xiii.), and Picard (chapter xiv.). An account, due to Jordan, is given of the application of the theory of substitutions to linear differential equations (chapter iii.). Many points are touched lightly here, a fuller development being held in reserve. A prominent feature is the reproduction (chapter vii) of a thesis by M. E. Goursat on equations of the second order satisfied by the hypergeometric series. This consists of two parts. The first part gives an application of Cauchy's theorem, and relations between Kummer's (24) integrals, an application to the complete elliptic integral of the first kind, and Schwarz's results. The second part discusses the transformations of the hypergeometric series, Tannery's theorem, and some other points, the article closing with a collection of 137 transformations due (apparently) to Kummer.

The pages bristle with references to original sources, so that, as we have already indicated, this treatise is an invaluable handy-book to what has been done in this field.

One more word: there is no collection of examples for solution on the Cambridge model, but the work is strictly on the lines of a French or German treatise.

The book itself is very elegantly turned out.

[1] For instance, he obtains certain forms in the same way that Fuchs obtained them, "if for no other reason than that of the desirability of developing the subject in historical order" (p. 64).

THE BACTERIA OF ASIATIC CHOLERA.

The Bacteria of Asiatic Cholera. By E. Klein, M.D (London: Macmillan and Co., 1889.)

SO masterly and complete was the account which Koch gave in 1884 of the comma-bacillus, which he held to be the virus of cholera, that but little, if anything, has been added to our knowledge of its mode of growth, of its reaction to dyes, or of its life-history. As might be expected, the assiduity of many observers, now it has been directed to the subject, has led to the discovery of many other bacilli, which may be described as comma-shaped. But, so far, no bacteriologist, who has had his observations corroborated by other observers, has proved that any of them are indistinguishable in all their physical characters, whether in appearance, in reaction to dyes, or in their mode of growth, &c., from the choleraic bacillus. So far as is known, animals are not susceptible to cholera. If Asiatic cholera could be induced by inoculating with pure cultivations of choleraic comma-bacilli, then beyond a doubt they would be the *vera causa*, or, in other words, the contagium of cholera; but this step in Koch's argument was wanting, probably for the above-named reason, and is likely to remain so; the experimental inoculations of guinea-pigs which have taken place being by no means conclusive.

The present volume is a valuable and most trenchant criticism of every step of Koch's argument, and may be said to contain everything that can at present be said against Koch's theory, of which the author is the most active opponent.

The author commences with an account of the various comma-shaped bacilli which are at present known, and there are well-recognized characteristics which distinguish them from the first form, in all of them, except in those which depend upon solitary observations.

The following is the list of comma-shaped bacilli with the names of their discoverers:—

(1) Koch, in Asiatic cholera; ½ to ⅔ the length of tubercle bacilli, but thicker and curved. (2) Finkler and Prior, in cholera nostras; but Koch and Frank failed to demonstrate these in typical cases. They are thicker and longer than (1). In 10 per cent. gelatine, the growth is broad and conical, liquefying the gelatine more rapidly. (3) Lewis, in the fluid of the mouth, thicker than (1) Klein only twice has succeeded in growing them; every one else has failed. (4) Miller, in some cases of caries of the teeth, similar to (2). (5) Kuisl, in human fæces similar to (2). (6) Deneke, in stale cheeses. The growth on gelatine is similar, but they will not grow on potatoes. (7) Klein, in some cases of diarrhœa, especially in monkeys. They grow differetly in gelatine, and cause it to smell offensively. (8) Ermengen and others, in the intestines of guinea-pigs, pigs, rabbits, horses, &c., but they will not grow in 10 per cent. gelatine. (9) Lingard, two kinds in a case of noma, the smaller of which is said to have been very similar to the choleraic one. (10) Weibel, various forms in mucus, but their mode of growth is distinct. (11) Gamaleïa, in a fatal fowl disease, which was prevalent at Odessa. He did not distinguish them from (1). (12) Klein, in the intestines of a monkey with diarrhœa. The organisms were smaller, but the growth was similar to (1).

Klein lays great stress upon the difficulty there is in demonstrating the presence of the bacilli in the walls of the intestine in cases of cholera, and thinks that they are not present in the parts which are still alive, but only where the tissue has died; moreover they are absent from the blood.

The bacilli are most readily found in the mucous flakes; and in the presence of fæcal matter they are

readily destroyed, which may explain why they are sometimes not easily detected.

The author has done good service in threshing out all the evidence afresh, but the matter remains very much where Koch left it. The detection of the bacilli may enable us more readily to diagnose the earliest cases in an epidemic of cholera; and, as one result of his experiments, we may expect soiled linen to be most efficiently sterilized by drying it; at the same time, until the disease has been reproduced by inoculation with the organism, it cannot be said to be conclusively proved that this is the true virus.

OUR BOOK SHELF.

Manuel de l'Analyse des Vins. Par Ernest Barillot. Pp. xii–131. (Paris: Gauthier-Villars et Fils, 1889.)

THE student of practical chemistry will find in this book a handy guide to the examination of wines. Works on the same subject are frequently rendered both unwieldy and tiresome by a multiplicity of analytical methods and the introduction of a bulky collection of tables embodying the composition of various classes of wine, a knowledge of which is deemed necessary in forming an opinion of the quality or purity of a particular sample. Here, however, details of this kind are reduced to a minimum. One or two methods, only, of carrying out any estimation are given, and free use is made of such empirical relations between the proportions of the constituents of a wine as seem warranted by the results of previous analyses.

The book consists of two parts and an appendix. Part I. is concerned with the determination of the normal constituents of wines, alcohol, total solids, ash, grape sugar, &c. Part II. deals with adulterations. In its opening sections are placed the indications traceable to the presence of added water, added alcohol, cane sugar dextrine, &c., but the greater bulk of the part is devoted to the detection of foreign colouring matters. The subject of colour reactions is very fully treated, and by the arrangement of the experiments in tabular form their nature and interpretation can be readily appreciated. It seems a pity that in connection with these tests no notice is taken in the text of the absorption spectrum of the colouring agents, as a clue to their identification; in a footnote the author contents himself by merely referring the reader to the works of Vogel and Wurtz for information on this subject. In the appendix is a statement of the chemical constitution of the colouring matters mentioned, followed by an account of some recent work of the author on the detection of added alcohol. His method is based on the effect of the alcohol introduced on the proportion of volatile acid which distils from the wine, and the result is shown to be consistent with the theory of the rate of etherification of organic acids.

The book is intended to be useful for commercial purposes, and for such the analytical processes described are sufficiently accurate. The apparatus employed, as is stated in a footnote, has been constructed by the Société Centrale de Produits Chimiques, and judging from the illustrations, is in some cases, to English eyes at least, a trifle antiquated. The occasional reference to vessels provided with marks, and to which no numerical values are attached, detracts somewhat from the general usefulness of the book, and is unintelligible to a reader who has failed to notice the explanatory footnote.

The graduation of alcoholometers, the maximum amount of alcohol permissible in wines, &c., are of course in accordance with the regulations of the French Excise.

Synoptical Tables of Organic and Inorganic Chemistry. Compiled by Clement J. Leaper, F.C.S. (London: George Gill and Sons, 1890.)

THE compiler says in his preface that "the mass of facts presented to the mind of the beginner in chemistry is so large that he often experiences a difficulty in distinguishing the useful from the ornamental, and is apt, consequently, to neglect fundamental principles and reactions for comparatively useless minutiæ. These tables are intended to prevent this error. . . . The experience of many years has convinced the author that the student who honestly commits these tables to memory will lay for himself a solid groundwork for future reading and research." Whatever may be meant therefore by the expression "future reading and research," it appears that the compiler aims no higher than to give a series of unconnected statements which if learned will enable the would-be student to begin his study of chemistry. We do not think this committing to memory will make the study more easy, and should fear that the learner might imagine after his memory exercise that he thereby knew something of chemistry. The separation of "the useful from the ornamental" is always difficult, and it is rare to find two authorities at one in such a matter. It is doubtful, for example, whether any chemist will agree with the compiler when he states as Charles's law that "All gases expand or contract $\frac{1}{273}$ of their volume for each rise or fall of 1° C.," and omits, presumably as ornamental, the limitation of this proportion to the volume of the gas at 0° C.

The British Journal Photographic Almanac, 1890. Edited by J. Traill Taylor. (London: Henry Greenwood and Co., 1890.)

IN this year's volume we find a most interesting collection of notes and articles relating to almost every branch of the subject. Captain Abney contributes an article in which he warns photographers to beware of their principal enemy—dust—and concludes with the best method of exclusion. The Rev. S. J. Perry gives a short summary of the instruments used in celestial photography during the past year, and of the work accomplished, including the wonderful photographs taken by Isaac Roberts of the nebula of Andromeda, nebulæ in the Pleiades, &c. Mention is also made of the success of Mr. Common in rendering still more perfect the reflecting surface of his magnificent five-foot glass mirror. Amongst the other articles we may refer to that on halation by Chapman Jones, hydroquinone by W. B. Bolton, and celluloid films by Colonel J. Waterhouse. An epitome of the year's progress, with notes on passing events, original and selected, is given by the editor, who marks the great advance made in film photography, and also the tendency to diminish the bulk of cameras, as shown by the innumerable hand or detective cameras that have appeared during the last twelve months. Allusion also is made to the new developer, eikonogen, which can, it is believed, develop into full printing density a plate that has been impressed by feeble radiations.

No alteration has been made as regards the general order of the work; there are only slight additions to the tables, formulæ, &c. The specimens of processes which illustrate the volume, especially that of Mrs. Sterling from a negative by Vander Weyde, are very fine.

Four-Figure Mathematical Tables. By J. T. Bottomley, M.A., F.R.S., &c. Second Edition. (London: Macmillan and Co., 1890.)

THIS useful collection of tables has been considerably enlarged and revised since its first appearance. It comprises logarithmic and trigonometrical tables, tables of squares, square roots, and reciprocals, and a collection of useful formulæ and constants. The introduction is suffi-

ciently detailed to make the construction of the table readily understood, assuming a knowledge of the use of logarithms. The book will prove a handy substitute for more bulky volumes in cases where extreme accuracy is not required, such as computations in chemistry and physics.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Panmixia.

MY letter of March 6 commenced with the remark that, without entering into controversy, I proposed to draw attention to the opinions expressed concerning the inheritance of acquired characters by Mr. Darwin. The reasons for my own beliefs on the questions at issue I have given in "The Principles of Biology," § 166, and, with other illustrations, in "The Factors of Organic Evolution." Here it must suffice to say that I have seen no reason to abandon the conclusions there set forth.

Respecting the doctrine of "panmixia," either as enunciated by Prof. Weismann, or as recently presented in modified forms, I will say no more than that I should like to see its adequacy discussed in connection with a specific instance—say the drooping ears of many domesticated animals. "Cats in China, horses in parts of Russia, sheep in Italy and elsewhere, the guinea-pig in Germany, goats and cattle in India, rabbits, pigs, and dogs in all long-civilized countries, have dependent ears."

Here the influence of natural selection is almost wholly excluded; nor can artificial selection be supposed to have operated in most of the cases: save, perhaps, in some pet animals, selection has been carried on to develop other traits. In the cases of most of these creatures, too, artificially fed and often over-fed, it does not seem that individual fates can have been affected by economy of nutrition, either general or special; since there has been no struggle for existence to cause the survival of those in which nutriment was most advantageously distributed. Further, the parts in question are not of such sizes that economy in nutrition of them could sensibly affect the fates of individuals, even had the struggle for existence been going on. Again, it seems that in respect of the ears themselves (though not in respect of their motor muscles) there has been extravagance of nutrition rather than economy of nutrition; since even where selection has been carried on for increasing other traits, the ears have not dwindled but rather increased. Lastly, at the same time that there has been this surperfluity of nutrition in the ears themselves, their motor muscles appear to have dwindled either relatively or absolutely—at least relatively, we must suppose, where the weight of the ears has increased, and absolutely where the weight of the ears has not increased.

The question presented by these facts is one in the solution of which the theory of "panmixia" may, I think, be satisfactorily tested; and without expressing any opinion upon the matter myself, I should be glad to see it discussed.

HERBERT SPENCER.

I AM not aware how far Prof. Ray Lankester is disposed to acknowledge his obligations to Prof. Weismann for what I am glad to see he now calls his "anti-Lamarckian" (as distinguished from "pure Darwinian") proclivities. Therefore I do not know how far he professes to be one of "the followers of Prof. Weismann," to whom my previous letter on this subject was addressed. But it seems desirable that I should take some notice of the altogether distinct question which he has now raised—viz. whether, or how far, Prof. Weismann's anti-Lamarckian views were anticipated by Mr. Darwin.

His argument is that Darwin must have been a Lankesterian anti-Lamarckian in disguise; and, more particularly, that "the doctrine of panmixia is recognized and formulated in the last (sixth) edition of the 'Origin of Species' published in 1872."

Taking the most general statement first, Prof. Lankester represents it as not improbable that "when Darwin refers, here and there throughout his works, to a reduced or rudimentary condition of an organ as 'due to disuse,' or 'explained by the effects of disuse,' he does not *necessarily* mean such effects as the Lamarckian second law asserted and assumed (though often he does appear to mean such); but he may mean, and probably had in his mind, the effects of disuse as worked out through panmixia and economy of growth."

Now, here we have a specimen of Prof. Lankester's dialectic at its worst. Truly, with such an interpreter, Darwin "*may*" be made to "mean" anything. First it is represented as seeming "not at all improbable that when Darwin refers" to one principle, "he does not *necessarily* mean" what he says; and then it is concluded that "he may mean, and *probably* had in his mind a totally different principle." Moreover, what is represented as mere references, "here and there throughout his works," are, as all the world knows, one whole and "highly important" (though still subordinate) side of Darwin's system. Yet again, in all passages where the meaning assigned to his term "disuse" is explained, there can be no shadow of ambiguity attaching to it, and everywhere it is alluded to as a principle wholly distinct from the "economy of growth"; while panmixia, as I shall presently prove, is nowhere mentioned at all. This, indeed, is clearly shown even in the passages quoted by Prof. Lankester, and now re-quoted below. For it is there said that, could a certain explanation be found, "then we should be able to understand how an organ which has *become useless* would be rendered, *independently of the effects of disuse*, rudimentary." Obviously, in this context, "the effects of disuse" cannot possibly mean "the effects of disuse as worked out through panmixia and economy of growth": they *can* only mean the direct effects of disuse itself in causing inherited atrophy. And now, lastly, "the effects of disuse" are habitually pointed to by Mr. Darwin in association with the "effects of *increased use*"; and how he can "seem" to have "explained" *these* either by the economy of growth (which he fully recognized), or by panmixia (which he never recognized), I must leave Prof. Lankester to indicate.

It will be observed, from the point last mentioned, that this attempt to read the doctrines of Weismann into the writings of Darwin must equally collapse, whether or not any other human being can be found to follow Prof. Lankester in his commentary on Darwin's "here and there" references to "the effects of disuse": the equally constant and as frequently detailed references to "the effects of the increased use of parts, which I have always maintained to be highly important," are of themselves sufficient to dispose of the Lankesterian gloss. Nevertheless, it remains worth while to see whether there is any shred of evidence in support of the narrower or more particular statement, that the principle of panmixia is to be found "already indicated" in the "Origin of Species." The following are the passages upon which this statement is founded—passages, I may remark, which have certainly neither been "missed" nor "neglected" by me.

(1) "If under changed conditions of life a structure before useful, becomes less useful, its diminution will be favoured, *for it will profit the individual not to have its nutriment wasted in building up a useless structure*. . . . Thus, as I believe, *natural selection* will tend in the long run to reduce any part of the organization as soon as it becomes, through changed habits, superfluous, without by any means causing some other part to be largely developed in a corresponding degree" ("Origin of Species," sixth edition, p. 118).

(2) "Organs, originally formed by the aid of natural selection, when rendered useless, may well be *variable*, for their variations can no longer be checked by natural selection. . . . It is scarcely possible that disuse can go on producing any further effect after the organ has once been rendered functionless. Some additional explanation is here requisite, which I cannot give. If, for instance, it could be proved that every part of the organization tends to vary in a greater degree towards diminution than towards augmentation of size, then we should be able to understand how an organ which has become useless would be rendered, independently of the effects of disuse, rudimentary, and would at last be wholly suppressed; for the variations towards diminished size would no longer be checked by natural selection. *The principle of the economy of growth* explained in a former chapter [cited in quotation No. 1], by which the materials forming any part, if not useful to the possessor, are saved as far as possible, will perhaps come into play in rendering a useless part rudimentary" ("Origin of Species," sixth edition, pp. 401-402).

Can it be that Prof. Lankester has not even yet perceived the significance of "the idea" of panmixia? Such certainly seems to be the case from his use of the above quotations. For the words which I have italicized render it most obvious that the only principle under consideration is the economy of growth or nutrition, *i.e.* the *reversal* of selection: there is no allusion to panmixia, or the *cessation* of selection. In the second passage it is shown that, because "no longer checked by natural selection," useless organs will become *variable*; and hence that *if there were any other cause tending to degeneration* (such as the "impoverished conditions" subsequently suggested), natural selection would *not interfere* with—*i.e.* prevent or "check"—the degenerating process thus induced. But there is no hint that the mere cessation of natural selection must be *itself*, and in *all cases*, a cause of degeneration.

Similarly, at the end of his letter, Prof. Lankester again fails to distinguish between the cessation and the reversal of selection. For, after endeavouring to represent that Mr. Darwin did not understand my "view,"[1] he says, "it is not at all surprising that Mr. Darwin did not recognize any resemblance between it and his own statement, viz. that 'the materials forming any part, if not useful to the possessor, are *saved* as far as possible,' thus 'rendering a useless part rudimentary.'" Not surprising, indeed. But it is surprising that Prof. Lankester, even at this time of day, should thus appear incapable of clearly distinguishing between natural selection as *withdrawn* and as *reversed*. For this is the whole point, and the only point so far as "the doctrine of panmixia" is concerned. It is a matter of familiar knowledge that Mr. Darwin at all times and through all his works laid considerable stress upon the "economy of growth," (or, more generally, reversed selection); but, most emphatically, this is *not*, as Prof. Lankester now says it is, "the essence of the anti-Lamarckian view of the effects of disuse." The essence of this view is, and can only be, the *cessation* of selection, as Prof. Weismann has clearly perceived.[2]

In order that there shall be no doubt upon this point, I must here explain the importance of the *cessation* of selection, as distinguished from the *reversal* of selection, in regard to "the essence of the anti-Lamarckian view"—even though in so doing "I feel it rather a severe burden when I am called upon to expound the merest commonplaces of the subject under discussion."

As stated in my previous letter, "the principal evidence on which Mr. Darwin relied to prove the inheritance of acquired characters was that which he derived from the apparently inherited effects of use and disuse—especially as regards the bones *of our domesticated animals*." Now, the reason why our domesticated animals appeared to furnish the most unequivocal proof of the inherited effects of disuse (and so, likewise, of the inherited effects of use, as explained in my last letter) was this. In the case of all species in a state of nature, it is, as Darwin observed, impossible to eliminate the effects of natural selection (acting through the economy of growth, or otherwise) from those of disuse, supposing disuse to be a cause of degeneration in species as it is in individuals. Therefore, in order to estimate what, if any, is the proportional part that is played in degeneration by the inherited effects of disuse, it is necessary to find cases where disuse, if it ever acts at all, must be acting *alone*. Such cases Mr. Darwin took to be furnished by our domesticated animals, seeing that they are so largely protected from the struggle for existence on the one hand, while, "on the other hand, with highly-fed domesticated animals, there seems to be no economy of growth, nor any tendency to the elimination of superfluous details." Having found in such cases material for ascertaining the effects apparently caused by disuse *alone*, Darwin concluded that he was able to estimate the degree in which these effects occurred elsewhere, or generally; even though in all wild species they must usually be more or less associated with the effects of reversed selection. Therefore it was that he chose domesticated animals for all his weighings and measurings of comparatively disused parts—with the result of appearing to obtain good evidence of a high degree of reduction as due to the inherited effects of disuse alone. But it did not occur to him that the amount of reduction thus proved might be equally well explained, not indeed by the *reversal* of selection (as in wild species), but by the *cessation* of selection, or panmixia. And it is just because the cessation of selection thus applies with even more certainty to the case of domesticated animals, than does the reversal of selection to the case of wild animals, that the former principle is of such unique importance to "the essence of the anti-Lamarckian view": by its means, *and by its means alone*, can the apparent evidence of the inherited effects of disuse be overthrown.

Therefore, by seeking to assimilate the distinct principles of selection as withdrawn and selection as reversed, Prof. Lankester is performing but a sorry service to his anti-Lamarckian cause. Weismann may well cry, "Save me from my friends," when he finds them thus playing into the hands of his opponents. For on all the logical bearings of his principle of panmixia, Weismann has perfectly clear and accurate views; and although he was not accurate in representing the relations which obtain between this principle and that of reversed selection, such is but a small error compared with Lankester's identification of the two principles—with the necessary result of again bringing into court the whole body of direct evidence on which Darwin relied in his apparent proof of Lamarck's "second law."

We shall now, perhaps, be able to understand what Prof. Lankester means when he says: "The idea [of panmixia] occurred to me also shortly after the passages above quoted from Mr. Darwin were published." If this is the case, "the idea" in question must have "occurred" to Prof. Lankester before he had reached his teens, seeing that one of "the passages" in question is not confined to "the last edition of the 'Origin of Species,'" but runs through them all. Allowing this to pass, however, what I have now to remark is, that if the idea which occurred to Prof. Lankester "shortly after the publication of that work" (1872) was, as he alleges, the idea of panmixia, it becomes a most unaccountable fact that in his laborious essay on "Degeneration" (1880) there is no hint of, or even the most distant allusion to, this idea. Yet, in the presence of this idea, "Hamlet" without the Prince of Denmark would be a highly finished work compared with an essay on "Degeneration" without any mention of panmixia. Therefore, here again, I can only understand that Prof. Lankester has not even yet assimilated "the idea in question." He confounds this idea with that of the economy of growth: he fails to perceive the very "essence" of the idea, in the all-important distinction between selection as withdrawn and selection as reversed. Without question, his essay on "Degeneration" proves a familiar acquaintance with the doctrine that "the materials forming any part, if not useful to the possessor, are saved as far as possible"; but, most emphatically, this is *not* "the idea of panmixia," while it *is* the idea that is definitely "formulated" scores and scores of times through all the editions of Mr. Darwin's works—an "idea," therefore, which must necessarily have "occurred" to every reader of those works since the time when Prof. Lankester was at school.

As this letter has already run to an inordinate length, I will relegate to a footnote my discussion of the merely personal criticisms which Prof. Lankester has passed upon my former communication.[1]

GEORGE J. ROMANES.

London, March 28.

[1] There is something comical to me in this endeavour, in view of all the conversations and correspondence which I had with Mr. Darwin upon the cessation of selection. Moreover, I do not in the least agree with Prof. Lankester where he says that my "view, as it appears in Mr. Darwin's words ('Variation,' &c, vol. ii. p. 309), is certainly *not* the same as that which Mr. Romanes has expounded in NATURE of March 13, 1890." That my "view" is not *fully* given, Mr. Darwin himself affirms; but, "as far as it can be given in a few words," it is given as correctly as I could wish.

[2] It appears to me that Prof. Lankester cannot have read Prof. Weismann's exposition of "the doctrine of panmixia." For, not only does he make this otherwise unaccountable (and, in relation to his "anti-Lamarckian view," suicidal) blunder of seeking to unite, if not virtually to identify, the principles of panmixia and economy of growth; but he alludes to Weismann as having "stated briefly" the former principle. "Stated briefly" it certainly is in "the translated essays"; but this is only because it is set out at length in one of the untranslated essays, which is entirely devoted to expounding the matter ("Ueber den Rückschritt in der Natur"). And this reminds me that in his review of Mr. Wallace's "Darwinism" there is a passage which similarly indicates that Prof. Lankester has either not read, or has strangely forgotten, another of Weismann's unpublished essays. Therefore, seeing how ready he is, on account of a precisely similar omission, to jump upon Mr. Herbert Spencer—whose recent and protracted illness is notorious—one can scarcely refrain from asking in his own words, "Will not Mr. Spencer and *others* who are interested in these matters read Weismann's essays?"

[1] Prof. Lankester says:—"As soon as the matter had taken root in his mind, Mr. Romanes published in NATURE, March 12, April 7, and July 2, 1874, an exposition of the importance of the principle of cessation of selection as a commentary upon a letter by Mr. Darwin himself (NATURE, vol. viii. pp. 432, 505), in which Mr. Darwin had suggested that, with organisms subjected to unfavourable conditions, all the parts would tend towards reduction. Mr. Darwin, with his usual kindly manner towards the suggestions of a young writer, gives, at p. 309 of vol. ii. of 'Animals and Plants under Domestication,' Mr. Romanes's view, 'as far as it can be given in a few words.'" Now, as it is only a few days ago that I myself directed Prof.

The Spectrum of Subchloride of Copper.

It is noticed in NATURE (vol. xli. p. 383), as the substance of a paper read to the Academy of Sciences in Paris, on the 10th ult., by M. G. Salet, on the blue flame of common salt, and on the spectroscopic reaction of copper-chloride, that the strongest lines of the former flame, in the indigo and blue, are due to copper-chloride, and coincide with bands given in M. Lecoq de Boisbaudran's "Spectres Lumineux."

Copper and chlorine appear, from the easy formation of copper-subchloride, to have a very unstable affinity for each other; and the readiness with which copper itself seems to volatilize, as shown by Mr. John Parry, in his spectroscopic experiments for the Ebbw Vale Steel-making Company in Wales, on the detection of impurities in iron and steel, by the free and wide diffusion of its vapours compared with those of other metals to a distance from a blowpipe flame, would perhaps tend to promote dissociation and to the production of subchloride from chloride of copper, at least in the presence of reducing-gases, in a flame.

There is a considerable general resemblance in respect of place and brightness between the groups of lines belonging to chlorine, and those belonging to copper-chloride, as those two spectra are represented in M. Lecoq de Boisbaudran's work. But the two spectra are of course very far from showing any precise coincidences with each other. My attention was drawn some time ago (in July 1878, NATURE, vol. xviii. p. 300) to a set of line bands of this same description, in very near correspondence, apparently with the chief lines of the copper-chloride spectrum, which presented itself in a violet-blue flame seen very frequently in ordinary fires when they have been fed with almost any kind of household dust and rubbish. But the remarkably neat triplet of line-pairs—green, blue, and indigo—in this blue fire-flame's spectrum could only be recognized as very indistinctly matched by those chief lines of the spectrum of copper-chloride, as those are produced, for instance, by introducing into a Bunsen-flame a piece of copper-foil well wetted with hydrochloric acid; and no counterpart at all to them, any more than to the ordinary chloride of copper spectrum, could be traced in the well known blue fire-flame of common salt, in whose spectrum, when pure, as well as in that of the equally familiar blue fire-flame (when pure also) of carbonic oxide, I do not remember to have ever detected any lines or bands of greatest brightness so obviously discernible and distinct as to admit of measurements.

In the case of a copper-melting furnace, round the loose junction of whose lid small escaping bodies of blue flame, on one of the days on which I analyzed them, showed the well-defined triplet spectrum very neatly, it was afterwards mentioned to me (when that observation had been noted at the above place in NATURE), that pieces of ships' old copper-sheathings were sometimes put into the copper-melting pot; and just as the use of logs of broken-up ship-timber (as was also stated at that place in NATURE) explained a gorgeous blaze of this flame's fine blue colour in a London house-fire very satisfactorily, so foreign importations by salt into waste-materials from seaworn ships, might by such a practice's occurrence as this in the melting furnace, account very well for the presence of chlorine along with copper in the furnace efflagrations which showed the neat and easily recognized line-spectrum on one of the days of my spectroscopic examinations of them, very plainly. Neglected scraps of brass and copper become, however, so soon contaminated with chlorine in nearly all situations, that it suffices, in general, to throw any rusty piece of them, such as an old, dirty piece of thin brass or copper wire, among the glowing coals of a bright fire, to produce this peculiar-spectrumed blue flame in the hottest crevices of the fuel.

The nature of this flame, since it differs very materially, by the simplicity of its spectrum, from the ordinary one of chloride of copper, although in the strong point of line-positions there is a partial feature of similitude in the spectra of the two flames by which they agree very nearly with each other, remained a mystery to me for several years; but about four years ago I chanced by good fortune to hit upon a compound, in some experiments on subchloride of copper, which yielded in a flame, at least a successful imitation, if not, as seems most probable, the really natural and perfectly exact reproduction of it. Copper subchloride is easily obtained by evaporating hydrochloric acid to dryness in an open dish on an excess of wire clippings or other small fragments of metallic copper. It is a dark greenish-brown powder, which easily deliquesces, and by absorbing oxygen, if exposed to the air, is soon converted into the green chloride of copper. For the spectroscopic purpose it should be dissolved when first formed, and dry, in about its own weight of hot glycerine, and the solution be allowed to cool in a well-corked bottle. This pasty solution inflames, when heated on a wire, and burns with the peculiar-spectrumed violet-blue flame which is observable in common fires when contaminations of copper by chlorine are introduced among the fuel, in its hottest parts. Although these contaminations in the state of exposure to common air probably all consist of ordinary chloride of copper, yet among the interstices of the fire, by the presence of hot fuel and great abundance of carbonic oxide, they doubtless undergo reduction to subchloride, and, in place of the many-lined and banded green-flaming spectrum of ordinary copper-chloride, the far simpler and symmetrically grouped one of three line-pairs—green, blue, and indigo—belonging to subchloride of copper vapour presents itself in the fine blue tint which the fire's flames assume, one may suppose, by chloride's reduction to subchloride, and by the infinitesimal admixture in them of this latter foreign substance. The varieties of tint, from blue below to green above, which a Bunsen-flame exhibits when chloride of copper is introduced into it, are probably due to the same chemical conversion, in dependence on the reducing or oxidizing constitution of the flame in its inner and outer layers, which most purely exhibit the two different colorations.

To produce the subchloride of copper spectrum very purely, the thinnest possible smear of its pasty solution in glycerine, on one side of a narrow strip of paper, suffices very amply, since its colouring effect upon the flame, when the strip is rolled up into a spill and lighted, is very powerful. Chlorate of potash powder, kneaded up with the glycerine solution, burns also self-supportingly with the characteristic rich blue colour, but the spectrum in this case, and also when the paper stain of the glycerine solution is left long exposed to air upon the strip.

Lankester's attention to this passage, and as it appears evident that he has not referred to my original letters in NATURE, I conclude that he does not know how completely I there recorded my obligation to the article by Darwin which really first did engender the doctrine of panmixia. But, be this as it may, the following is what I wrote:—

"In a former communication I promised to advance what seemed to me a probable cause—additional to those already known—of the reduction of useless structures. As before stated, it was suggested to me by the penetrating theory proposed by Mr. Darwin, to which, indeed, it is but a supplement" (1874).

Again, in 1887, while anticipating and greatly extending Prof. Lankester's present criticism touching Mr. Spencer's attitude with respect to panmixia, I said:—

"The leading idea in Mr. Darwin's suggestion was that impoverished conditions of life would accentuate the principle of economy of nutrition, and so assist in the reduction of useless structures by free intercrossing. Now, in this idea, that of the cessation of selection was really implied; but neither in his own article, nor in a subsequent letter by Mr. George Darwin on the same subject (NATURE, October 16, 1873), was it exhibited as an independent principle. It was inarticulately wrapped up with the much less significant principle of impoverished nutrition."

The simple history of the matter, therefore, is as follows. Even up to the time of publishing his article in NATURE, Mr. Darwin had not perceived the principle of panmixia as an "independent principle"—any more than Dr. Dohrn perceived it in 1875, or Prof. Lankester perceived it in 1880,—which must act in all cases of degeneration, whether with or without the co-operation of reversed selection in the economy of growth, "impoverished conditions," &c. Therefore, in the sixth edition of the "Origin of Species," after having explained the phenomena of degeneration by the inherited effects of disuse, combined with the economy of growth, he proceeds to give very good reasons for concluding that "some additional explanation is here requisite which I cannot give"; and he suggests that, "*if it could be proved* that every part of the organization tends to vary in a greater degree towards diminution than towards augmentation of size, *then we should be able to understand* how an organ which has become useless would be rendered, *independently of the effects of disuse*, rudimentary," &c. But although he thus saw the "explanation" that was "requisite," he said he was unable to give it; therefore at that time he could not have seen that the cessation of selection was exactly the explanation of which he was in search—to wit, a principle which must always make every unused part of the organization tend to degenerate. Later on, however, it occurred to him that "impoverished conditions," *combined with intercrossing*, might lead to this result. But, although he thus came to such close quarters with the idea of panmixia that he immediately suggested it to me on reading his exposition, the idea was still entangled with that of "impoverished conditions" being required in order to *starve* the degenerating parts. Therefore, the only hand that I had in the matter was to liberate the all-important principle of panmixia from the toils of this entanglement, and thus to show that it must necessarily act in the case of *all* unused structures, with the result of destroying the evidence of "the effects of disuse."

Such is a simple history of the facts; and my only object in previously alluding to the part which I had played in the matter was not that of claiming priority touching so very obvious an "idea," but in order to show how it was that Mr. Darwin, through all the editions of the "Origin of Species," continued to attribute important weight to a line of evidence in favour of the inherited effects of disuse, which the doctrine of panmixia, *and the doctrine of panmixia alone*, has entirely destroyed.

of paper, is apt to lose its purity and acquire confusing lines and bands of ordinary copper-chloride, by oxidation, which the preparation then undergoes spontaneously, before igniting it. For pyrotechnists, therefore, it seems scarcely probable that the subchloride of copper, with its pure cerulean flame, will ever be of any very useful value. But as a parallel example of a coloured-fire composition, it may be mentioned here, that powdered Val Traversite (a bituminous limestone found near Neuchatel, in Switzerland), on account of its prodigious natural richness in bitumen, when mixed with sufficient chlorate of potash, also burns self-supportingly, with a fine orange-red flame in which the familiar spectrum of calcic oxide is, of course, most vivid. Were hot asphalt, pitch, or bitumen, instead of hot glycerine, used to dissolve or to "masticate" the dry subchloride of copper when it is freshly made, a copper-chlorinated mass would be produced which would probably be capable of resisting atmospheric action, and whose mixture with chlorate of potash would, like the similar Val-Traversite mixture, probably also not suffer by keeping and exposure, and would furnish a source of blue flame and of the significantly simple spectrum of subchloride of copper, not less vividly true and fixed in their distinctness, than the orange-red light and strongly pronounced calcic-oxide spectrum of the other combination of chlorate of potash with a bitumen-containing substance.

As regards the blue salt-flame, whose spectrum in its purity shows no conspicuous lines, or bands of greatest brightness, it can hardly be doubted that the element chlorine, from the positions of its own principal line groups, contributes mainly to produce the blue coloration, at a temperature, in the fire, which is not high enough to dissociate the sodic chloride and liberate sodium vapour, with its tell-tale yellow line, from its chemical union. In the green flame of chloride of copper the colouring groups of lines show a more detailed resemblance than this to the chief colorific lines in the elementary chlorine spectrum,[1] while in copper subchloride's "bluest of blue" flames, the wide green light-bands of copper chloride fade out, leaving the colorific light concentrated almost entirely in three close pairs, or in six bright lines, which, if they do not coincide in place with, are at least not far distant in position from, three chief line-pairs in the ordinary spectrum of chloride of copper. There is much in these resemblances which betokens some kind of continuity of connection with the primary features of the chlorine spectrum itself; the evidences of which, although thus displayed by copper and chlorine in the spectroscope, may perhaps be sensibly regarded as having some near relation of analogy to the appearance of variable chemical combining power under the influence of light, between silver and chlorine, presented in photography. But there is also, undoubtedly, a very marked distinction between the "spectroscopic reactions" of these two different copper chlorides; and, similarly, there are in the apparently mutable photochemical affinity between silver and chlorine in photography, two fairly stable delimitations of its range, in the "subchloride" (or as it has been termed by Mr. Clement Lea, the "photochloride") of silver, and in ordinary silver-chloride. Further discriminations of the copper-chloride spectra in intermediate forms which they seem to comprise transitionally between the two definite ones of the chloride and subchloride, would perhaps extend and strengthen this analogy, and may not impossibly help, at some future time, to explain and illustrate it, if there is any real soundness in it, more fully and completely.

The example of fluoride of calcium is a curious one in spectrum analysis, where sprinkling fluor-spar dust in a Bunsen-flame produces, in addition to the normal calcic oxide spectrum of one orange-red and one green band, a second bright and narrow green one at a distance from the first about equal to that of the red band from it. There are no other distinguishable bands. But if the pair of normal ones is really due to calcium-oxide vapour produced by decomposition in the flame, it is not very easy to conjecture to what other product of decomposition the additional, sharply defined and brilliant, solitary green band can be ascribed. The spectrum of hydrofluosilicic acid gas presents a very gorgeous band-array of violet-blue lines, whose lustrous group is probably indicative of near neighbourhood in place to some bright line concentration in the spectrum of fluorine itself; but if so, the collection of its colorific strength in the single additional green line of the fluor-spar spectrum, seems to imply a freedom from uniformity in fluorine's power of imparting spectral coloration to its compounds, just opposite to the sensible continuity and kinship of spectral clusterings, above described, which the presence of chlorine appears to impose upon its compounds by common resemblances discernible in the blue light-ascendencies of the fire-flames of common salt, chloride and subchloride of copper, when they are spectroscopically analyzed.

A. S. HERSCHEL.

Observatory House, Slough, March 3.

[1] A very suggestive example of a substance's detection by recognition of its spectrum was described, with a drawing of the recorded spectra, by Mr. A. Percy Smith, in a short notice of a series of observations on the spectra of chlorides, and on the blue flame of common salt, in the *Chemical News*, vol. 39, p. 141 (1879). An examination of the flame-spectra of several different chlorides, enabled the author of that notice to recognize a common similarity among them all to the spark- or flame-spectrum of hydrochloric acid gas. This gas showed a belt of green line-bands which agreed in their main positions with the green portion of a long array of band-pairs shown with much constancy by several different alkaline and earthy chlorides, and especially by ammonium chloride, and by mercurous chloride (or calomel, where the agreement was also verified by a direct comparison), in a Bunsen flame; but no line-counterparts to the equally bright, blue-lined portion of the same constant spectral striation were observable in the hydrochloric acid spectrum.

From the easy conversion of chlorides into the corresponding oxides in an air-gas flame, when the flame is not kept artificially saturated with hydrochloric acid gas, we might pretty certainly assume that in the flame's ordinary condition, the heated chlorides would always disengage sufficient chlorine to produce by combination with hydrogen in the coal-gas of the flame, traces of the stable product, hydrochloric acid gas, among the gases of the flame's combustion; and the different chlorides would thus, by suppositions which may not perhaps be unlikely and inadmissible, all supply the flame alike with the substantial factor needed, for the appearance of the green line portion of the constant spectrum.

At the same time new carbon-compounds would be formed by dehydration of the flame's gaseous hydrocarbons, to furnish hydrogen to the liberated chlorine, and some constant carbon-gases then, of not yet known descriptions, might be conjectured just as comprehensibly and fitly, to be concurrently productive in the constant chloride-rank's illumination, of the blue-line portion of its bands, of which no spectral counterparts could be detected in the hydrochloric acid spectrum.

But whether the interesting figure and description given by Mr. A. Percy Smith in the above paper, of his long series of experiments, may or may not admit of such a simple spectro-chemical interpretation, the conflicts of contending chemical affinities of which the spectroscopic recognition of hydrochloric acid in flames fed with different chlorides furnishes such a wonderful example, give weight and value to the notes of the discovery recorded by Mr. A. Percy Smith, in a new wide field of the spectroscope's utility, which are of much deeper interest than any single theory to account only for this particular recognition and discovery itself.

Mr. A. Percy Smith's own capitally based, and clearly proved deductions from his numerous experiments, were accordingly, in prospect of their further prosecution, expressed thus, quite generally:—that the blue flame of common salt in a hot fire owes its coloration to reactions either exactly or very nearly similar to those which produce resemblance of a nearly constant spectral type in different chloride flames, to that of hydrochloric acid; and that, again, among the partly undetermined, and perhaps to some extent variable reactions which produce the similarity, there appear to be some which disturb and modify the ordinary appearance of the hydrochloric acid spectrum, and which would appear to superadd to it a series of blue line-bands which, as it is presented in a flame, or electrically in vacuum tubes, the spectrum of pure hydrochloric acid gas alone does not usually exhibit.

Brush-Turkeys on the Smaller Islands North of Celebes.

THE reviewer of Dr. Hickson's book, "A Naturalist in North Celebes" (March 20, p. 458), believes that the brush-turkey or moleo, *Megacephalon maleo*, has never been recorded as occurring in the smaller islands north of Celebes. I beg to remark that in the year 1879 I recorded this species from Siao, and in the year 1884 from Great Sangi, on both of which islands, besides, occurs a *Megapodius* peculiar to them, viz. *M. sanghirensis*, Schlegel, representing there *M. gilberti*, Gray, from Celebes (see the *Ibis*, 1879, p. 139; *Isis*, 1884, pp. 6 and 53, &c.). Perhaps Mr. Guillemard did not comprise Siao and Great Sangi under the head of "smaller islands," but Dr. Hickson himself (p. 95) records *two* brush-turkeys from the smaller island of Tagulandang, a larger and a smaller one, and these must be *Megacephalon maleo* and a *Megapodius*. Tagulandang is situated between Celebes and Siao, and much nearer to the latter island. From the volcano islet of Ruang, opposite and within about a mile from Tagulandang, he only records (p. 41) one brush-turkey, and this, of course, may be either the *Megacephalon* or a *Megapodius*, if both do not occur, as appears rather probable. When I visited Ruang in 1871 after the heavy eruption in March of that year (see NATURE, vol. iv. p. 286), nearly the whole of its forest was destroyed and burnt down, and I do not believe that a living brush-turkey then remained on the islet; but it has since been repeopled from its near neighbour, Tagulandang, where both species occur, and therefore, if the one could reach Ruang, the other may have reached it too. This is of no consequence at all. Dr. Hickson's following remark as to brush-turkeys on Tagulandang (p. 95), "The larger bird is perhaps the *Megapodius sanghirensis* of Schlegel, a brush turkey, which is bigger than the *Megacephalon*, and extends over the Sangir Islands," contains a mistake, as *M. sanghirensis* is much smaller than

Megacephalon maleo. The reviewer corrects, by the way, my calling the Celebean whimbrel *Numenius phæopus*, saying that it is probably *N. uropygialis*, but these two names are synonymical, cf. for instance, Salvadori, *Orn. Pap.*, iii., 332, 1882, *sub N. variegatus*. As to its nesting on small trees "small brushes" were intended to be implied (see Legge, "Birds of Ceylon," 1880, p. 913).

A. B. MEYER.

Royal Zoological Museum, Dresden, March 22.

Crystals of Lime.

IT was pointed out to me by Mr. W. J. Pope, of the City and Guilds of London Institute, that a lime cylinder which had been used in the lantern during a lecture had become distinctly crystalline where affected by the oxyhydrogen flame.

Examined under the microscope by polarized light, the crystals are seen to be well-defined cubes with striated faces. When immersed in water they break up and give rise to minute doubly refracting plates of rhombic outline, behaving in this respect like ordinary lime; the cubic crystals, however, are less rapidly affected by exposure either to air or water than is amorphous lime.

Lime is commonly stated to be infusible at the temperature of the oxyhydrogen blow-pipe; and the only crystals previously recorded, so far as I know, are those obtained by Brügelmann, by fusing calcium nitrate (*Annalen der Physik und Chemie*, ii. p. 466, iv. p. 277, 1877–78). It seems, therefore, worthy of notice that they are possibly always formed upon the surface of the lime cylinders by the action of the oxyhydrogen flame.

The crystals resemble in all respects those described by Brügelmann. The jet used on the present occasion was an ordinary blow-through jet.

H. A. MIERS.

Foreign Substances attached to Crabs.

I AM glad to see that Mr. Garstang agrees with me in regarding the presence of the Ascidians on *Hyas* as accidental.

I had no intention of decrying the value of Mr. Garstang's experiments with Ascidians, but his rule might, perhaps, be limited to those members of the group to which it can be proved to apply. Under natural conditions it apparently fails to apply to *P. corrugata* and *M. arenosa*. As to the latter, Prof. McIntosh assures me that he has frequently found it in the stomach of the cod and haddock.

The appreciation of the cod for *A. mesembryanthemum* is, I think, sufficiently proved by the fact that the latter is one of the most successful cod-baits used here.

ERNEST W. L. HOLT.

St. Andrews Marine Laboratory, March 29.

Wimshurst Machine and Hertz's Vibrator.

IT may interest those who wish to repeat Hertz's experiments on electro-magnetic radiation to know that many of these can be done very well by using a small Wimshurst machine in place of the usual induction coil and battery. The vibrator and resonator which we used were like those described in NATURE (vol. xxxix. p. 548), and the Wimshurst machine had two 12-inch plates (giving at most with the jars on a 4-inch spark). The wires from the vibrator, instead of being connected with an induction coil, were connected with the two outer coatings of the jars of the machine. The machine spark-gap and the vibrator spark-gap should be so adjusted that when a spark occurs at the former one also occurs at the latter. With the apparatus described we got good results when the spark-gaps were 38 mm. and 3 mm. respectively. The outer coatings of the jars are only connected together by the wood of the machine, but it is sometimes an advantage to put a few inches of damp string between the balls of the vibrator.

This combination is obviously a modification, adapted to work a Hertz vibrator, of one of Dr. Lodge's well-known Leyden jar arrangements.

No doubt many persons have connected the vibrator directly with the terminals of the machine, but this arrangement does not work nearly so well.

T. A. GARRETT.
W. LUCAS.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE annual meeting of the Institution of Naval Architects was held under the presidency of Lord Ravensworth, on Wednesday, Thursday, and Friday of last week. There was a fair list of papers on the programme, although at one time, shortly before the meeting, it was feared that there would be a sad lack of contributions from members. At the last minute, however, one or two papers came in, and the list, although perhaps below the average in the importance of the memoirs, was of passable interest.

The following is a consecutive enumeration of the business that was transacted at the meeting:—

Wednesday, March 26th: morning sitting—Annual Report of the Council, and other routine business; Address by the President. Paper read and discussed—Notes on the recent naval manœuvres, by Mr. W. H. White, F.R.S., Director of Naval Construction.

Thursday, March 27th: morning sitting—The Maritime Conference, by Rear-Admiral P. H. Colomb; strength of ships, with special reference to distribution of shearing stress over transverse section, by Prof. P. Jenkins; steatite as a pigment for anti-corrosive paints, by Mr. F. C. Goodall. Evening sitting—On the evaporative efficiency of boilers, by Mr. C. E. Stromeyer; on the application of a system of combined steam and hydraulic machinery to the loading, discharging, and steering of steam-ships, by Mr. A. B. Brown; the revolving engine applied on ship-board, by Mr. Arthur Rigg.

Friday, March 28th: morning sitting—On leak stopping in steel ships, by Captain C. C. Penrose Fitzgerald, R.N.; on the variation of stresses on vessels at sea due to wave motion, by Mr. T. C. Read; spontaneous combustion in coal ships, by Prof. Vivian Lewes. Evening sitting—Experiments with life-boat models, by Mr. J. Corbett; on the screw propeller, by Mr. James Howden.

The annual dinner was held on the evening of Wednesday.

Out of the above list of a dozen papers there were fewer than usual of scientific interest, and, indeed, in one or two instances they were not either distinguished by practical interest. Mr. White's paper, which formed the *pièce de resistance* of the meeting, was of military rather than scientific importance, and was chiefly notable from the number of admirals that took part in the discussion; indeed, the whole naval contingent of the Board of Admiralty was present to hear the paper read. Admiral Colomb's paper on the recent Washington Maritime Conference was practically reduced to a consideration of the rule of the road at sea. The general opinion of the authorities assembled appeared to be that the present rule of the road is very well as it stands, with the exception that the "holding-on ship" should not be required, or even allowed, to slacken her speed. This seems in conformity with common-sense. If two ships are converging towards a point, say at right angles to each other, and one shifts her helm to go under the other's stern, if the second, or holding-on ship, slacken speed, the probability will be that the giving-way ship will crash into the other's broadside or cross her bows; in the latter case, there is probability that the holding-on ship will give the other her stem. What is most wanted when danger of collision arises, is certainty on each vessel as to what the other may be going to do. If the holding-on ship never slacken speed—is not allowed to slacken speed—then the other vessel knows exactly what course to take; as the law stands, the quartermaster, or officer in charge, is never quite sure until the last minute, especially at night, whether the other ship considers there is danger of collision or not, and, therefore, whether she will slacken or keep to full speed. We anticipate the proposed alteration, if put in force, will greatly lessen the list of collisions.

The memoir contributed by Prof. Jenkins on the strength of ships was decidedly the most important contribution to naval science of this year's meeting. The paper will open up to the majority of those practi-

cally engaged in the design of ships a new field of research, the investigation of which will enable them to solve some problems which have hitherto been without explanation. That is, speaking generally—for the influence of longitudinal bending moment on shearing stress has before been investigated by naval architects; notably by Mr. W. H. White, the Director of Naval Construction, and Mr. W. John. This, however, was many years ago, and in connection with wooden ships with no longitudinal connection between the planking except that supplied by dowels, the friction of the edges, and the "anchor-stock" shape of the pieces. It will be evident, therefore, that previous investigations must have been of a qualitative, rather than of a quantitative, form; and the world of naval architecture is much indebted to the occupant of the John Elder Chair at Glasgow for putting the problem on a practical quantitative basis.

The paper contributed by Mr. C. E. Stromeyer had a most attractive title, "The Evaporative Efficiency of Boilers"; and a good many of the working marine engineer members of the Institution, who were acquainted with the thorough manner in which the author follows up all his work, had assembled to hear the paper read, and take part in the discussion. We are afraid it must have been somewhat of a disappointment to several of these gentlemen when they turned over the leaves of the paper as it was placed in their hands, and found that the matter was rather of a suggestive than of a conclusive character. There is so much business to be crowded into the three days' annual meeting of this Institution that it is necessary the papers should be read with despatch; and we quite sympathize with the engineer whose daily task is of an administrative rather than a contemplative nature, when he is asked to assimilate at a galloping pace two or three pages of mathematical formulæ of by no means an every-day character.

Mr. Stromeyer confined himself chiefly to a consideration of the relative distribution of efficiency in the tubes. He points out that the distribution is governed partly by the temperatures in the combustion-chamber and smoke box, and partly by the resistance of gas in the tubes, and this again depends upon the velocity and temperature of the gas, and on the loss of heat experienced by it. Mr. Longridge has found that the coefficient of transmission of heat through boiler-tubes or combustion-chamber plates is eleven calories of heat per square foot per hour for every degree F. of difference between the gas and the water: 0·091 is the reciprocal value, and is the resistance offered to the flow of heat under the above condition. This resistance is offered when heat passes from one medium to another, as, for instance, from the gas to the metal, from the metal to the boiler scale, or to the water, and it also includes the resistance offered by the metal to the scale. For iron and boiler scale the resistances are 0·00202 and 0·207 per inch thickness; so that a clean ½-inch plate would offer 0·001 resistance; or, if covered with scale one-tenth inch thick, the resistance would be $0·001 + 0·021 = 0·022$.

Arguing from these facts the author concludes that the chief resistance, about 80 per cent., is encountered at the surfaces; and he doubts whether the change of medium from iron to scale, and to water, influences the values very much. The chief difficulty in transmitting heat from the gas to the tubes is want of circulation, or admixture of gas in the tubes. He speaks favourably of draught retarders, corrugated tubes, and ribbed-tubes for the purpose.

Mr. Stromeyer next refers to the experiments of Haverez (see *Ann. du Génie Civil*, 1874), by whom it was shown that more heat is absorbed in the fire-box with flaming material than with flameless coke. It is well known that a luminous flame radiates more heat than one which is non-luminous; and it is for this reason that the latter may not be used in the Siemens-Martin furnace. For reasons given, Mr. Stromeyer would prefer that, in the formulæ used by Mr. Longridge for heating boiler tubes, the coefficient of resistance $\frac{1}{m}$ should be somewhat increased; say from 0·091 to 0·1. This the author works out in detail. We have stripped Mr. Stromeyer's arguments of their mathematical aspect, as, however interesting the matter may be, we have not space to do it justice. We must refer those of our readers who are sufficiently interested in the subject to the Transactions of the Institution.

Mr. Macfarlane Gray, of the Board of Trade, was the chief speaker in the discussion which followed. He said he could not pretend at one reading to follow the author in all his reasoning. Mr. Fothergill, who is the superintending engineer to a north country line of steamers, gave the meeting the benefit of his practical knowledge upon the subject. Mr. Fothergill is well qualified to speak on the question of the evaporative efficiency of marine boilers, as he has made an especial study of the matter in the actual working of vessels in connection with his well-known researches on the subject of forced draught on ship-board.

Mr. Brown's paper was one of unusual interest to the members of the Institution. In it he described the most recent development of that beautiful system by which he has so vastly improved the loading and discharging of cargo on steam-ships, and the steering of vessels. The paper was illustrated by several diagrams without the aid of which it would be impossible to make clear the details of the very ingenious methods by which the author has applied his combined steam and hydraulic practice to the purposes named. Briefly stated, it may be said that, in place of the usual deck winches, there is placed at every hatch a derrick, having mounted upon it the hydraulic cylinder which supplies the motive power to lift the goods. The steering motor is placed directly on the quadrant of the tiller, and is actuated from the bridge by means of what the author describes as a telemotor. The transmission of the controlling force which governs the steering motor is through hydraulic pipes; a vast improvement on the rattling chains and rods now in common use. In fact the great virtue of Mr. Brown's system is its quiet working.

Mr. A. Rigg's revolving engine is an ingenious device, perhaps better suited to water than steam. It was fully described in Section G at the last Birmingham meeting of the British Association.

"Leak Stopping in Steel Ships" was the somewhat misleading title of a rather weak paper by Captain Fitzgerald. The only point the author suggested was that war-ships should be outside sheathed with wood in order that there might be some attachment to which leak stoppers could be affixed. The contention that the swelling of wood by moisture that takes place, or used to take place, when a shot cut through the side of an old man-of-war is quite beside the mark, as we suppose no one proposes to make the wood sheathing of a modern steel steamer as thick as the sides of our old wooden walls. Three or four inches of elm would do very little swelling when pierced by a modern projectile of any considerable size.

Mr. T. C. Read's paper on the variation of stresses at sea is another of those contributions which are the despair of the practical naval architect, not over-given to abstruse science, who attends the meetings of his Institution, hoping to take part in the discussions. We are quite at one with the speaker, Mr. Alexander Taylor, who proposed that a rule should be passed compelling contributors to send in their papers sufficiently early for them to be printed and distributed to members before the meetings. The executive say it cannot be done, but it would be worth trying for a time.

Prof. Lewes's paper on the ignition of coal cargoes was quite a new departure in the practice of the Institution. When the members assembled they found an array of bottles, flasks, and chemical apparatus, that was not a little puzzling to those not in the secret, and must have reminded many of the dear old Polytechnic days and Prof. Pepper. However, the lecture, and the experiments by which it was illustrated, were of a thoroughly sound and practical nature. The question of spontaneous ignition of coal cargoes is one for the ship-owner rather than the ship-builder; excepting that ship-builders have to replace the vessels which are destroyed by reason of such spontaneous ignition. The lecturer illustrated the influence of carbon in producing heating by the power it possesses of attracting and condensing gases upon its surface. The action of the bituminous constituents of the coal in spontaneous ignition was next dealt with, and the author then proceeded to point out the important part the action of iron disulphide, pyrites, or coal-brasses played in promoting spontaneous ignition. The remedy Prof. Lewes advises for the evils of spontaneous ignition are: firstly, non-ventilation of holds, so that oxygen may not be admitted to carry on the chemical processes by which heat is generated; secondly, by placing thermometers, suitably protected, in the mass of coal, so that, by electrical communication, warning may be given when the temperature rises to a dangerous point; and, thirdly, by placing flasks of liquid carbonic anhydride in the coals, the flasks to be sealed by an alloy with a low melting-point. This would be fused when the dangerous temperature was reached, and the carbonic acid, in expanding to its gaseous state, would cool the mass of coal to a safe temperature.

At the last sitting of the meeting, Mr. Corbett's paper on lifeboat models raised a lively controversy. The Royal National Lifeboat Institution had brought Mr. G. L. Watson all the way from Glasgow to meet the bold innovator who proposed to abolish their cherished self-righting boats. Of course, who is right remained an open question, as it always does when the properties of lifeboats are concerned.

Mr. Howden's paper on the screw propeller was of great length, containing no less than twenty-four pages without the appendix. Mr. Howden, like many other people, has a theory of his own on the screw propeller, which is opposed to that of all other authorities on the subject; for he believes that Rankine, Froude, Cotterill, and others, have based their conclusions on erroneous premises. It will be evident that we cannot enter into this vast subject at the end of a notice such as this, but we may briefly record our opinion that the older authorities were right.

On the whole, the meeting passed off very well. The attendance was good, and Mr. Holmes, the secretary, had made his arrangements so that the business proceeded without a hitch, as, indeed, is invariably the case at this well-managed institution.

BOURDON'S PRESSURE GAUGE.

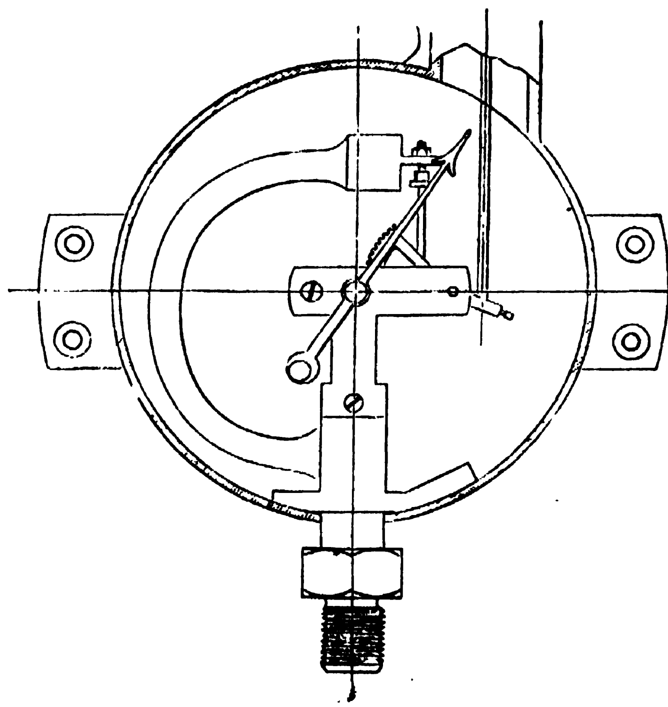
MR. WORTHINGTON'S letter to NATURE, January 30 (p. 296), on the theory of this instrument, has excited some criticism and disagreement of opinion; so it is proposed to examine here how far it is possible to construct a theory which shall be quantitative, in addition to giving a general explanation of the action.

The instrument is in very extensive use, hardly a steam-boiler being in existence which is not provided with one; and the simplicity and strength of the construction are such that it does not easily get out of repair, while it can be made to register either the highest pressure of the hydraulic press, or to record in the form of a barometer the minute fluctuations of atmospheric pressure.

The principle of the instrument was discovered by accident, and the account of this had best be given in the inventor's own words, taken from the paper read by him before the Institution of Civil Engineers, printed in the Proceedings I.C.E., vol. xi., p. 14, 1851:—

"The author had occasion to construct a worm-pipe for a still, by bending a cylindrical tube into a spiral or helical form. The workman performed the operation awkwardly, and partially flattened a considerable portion of the tube. In order to restore its form, one end was closed and the other was connected with a force-pump, by which water was forced into the tube; as the flattened portion of the tube resumed its cylindrical form, it was observed that the spiral uncoiled itself to a certain extent, and it was immediately perceived that this action might be applied to the construction of a pressure gauge."

To construct, then, a Bourdon gauge to register high pressures (*vide* figure, representing a gauge fitted to an indicator, not shown) a steel tube bored out of the solid bar to the requisite thickness for strength is taken, and purposely flattened, and then bent round into the arc of a circle so that the longer axis of a cross-section stands at right angles to the plane of the circle: one end of the



tube is screwed to a pipe which communicates with the liquid whose pressure is to be measured, while the other end is closed and joined by levers and racks to a shaft and a pointer, which traverses a dial on a box in which the curved tube is enclosed.

As the pressure in the tube is increased, the circular axis uncoils into a larger circle of smaller curvature, and the corresponding indications of the pointer on the dial are marked; and thus the instrument is graduated empirically by reference to some standard pressure gauge. As the pressure is again diminished, the elasticity of the tube brings it back to its original form, and the pointer retraverses the dial.

Lord Rayleigh gives an elementary explanation of the action of Bourdon's gauge in the Proc. Royal Society, No. 274, December 13, 1888; treating the movement of the walls of the tube as one of pure bending, he says:—

"In this instrument there is a tube whose axis lies along an arc of a circle and whose section is elliptical, the longer axis of the ellipse being perpendicular to the general plane of the tube. If we now consider the curvature at points which lie upon the axial section, we learn from Gauss's theorem (that in the bending without stretching of an inextensible surface, the

product of the principal radii of curvature of the surface at any point remains constant) that a diminished curvature along the axis will be accompanied by a nearer approach to a circular section, and reciprocally. Since a circular form has the largest area for a given perimeter, internal pressure tends to diminish the eccentricity of the elliptic section, and with it the general curvature of the tube. Thus, if one end be fixed, a pointer connected with the free end may be made to indicate the internal pressure." Lord Rayleigh adds, "It appears, however, that the bending of a curved tube of elliptical action cannot be pure (*i.e.* unaccompanied by stretching), since the parts of the walls which lie furthest from the circular axis are necessarily stretched. The difficulty thus arising may be obviated by replacing the two halves of the ellipse, which lie on either side of the major axis, by two symmetrical curves which meet on the major axis at a *finite angle*."

In fact some Bourdon gauges, notably those required for low pressures only, and requiring great sensibility but not much strength, are constructed in this manner, and the difficulty of manufacture is thereby considerably reduced. Barometers are constructed in this way, and give good results; the tube is partially exhausted of air, and closed at both ends; and now an increase of external atmospheric pressure tends to flatten, and thus curl up the tube.

In constructing any theory, we are then immediately brought up by the great difficulty at present engaging the attention of our mathematical elasticians, such as Rayleigh, Basset, Pearson, and Love; who are not agreed as to how far it is legitimate to theorize on the equilibrium of elastic shells, by treating separately the bending and the stretching as independent of each other, and considering the first—the bending—of the most importance.

If we take a piece of thin sheet metal in our hands, we find we can bend it with comparative ease, but any stretching we can produce is quite insensible; and it is thence argued that bending only is likely to take place, as so easily produced: and apparently reversing the ordinary mathematical procedure, the large stresses due to any stretching are neglected, as not likely to be in existence. These difficulties confront us in any attempt at a rigorous theory of the instrument, which would give quantitative results, enabling us to graduate the instrument from a formula.

The Rev. E. Hill has given in the *Messenger of Mathematics*, vol. i., 1872, an explanation of the Bourdon metallic barometer, treating the question as one of pure bending, and giving a quantitative formula for the change of curvature a of the total curvature θ in terms of the change x in the semi-minor axis b, viz. $a/\theta = x/b$. But the determination of x/b for a given change of pressure is as yet an intractable mathematical problem, even for the simplification of supposing the tube a straight elliptic cylinder.

When we attempt to determine mathematically the pure bending produced in an elliptic cylinder by an increase of internal pressure and consequent tendency of the cross-section to the circular form, we are baffled by the analytical difficulties of determining the change in the length of the axes of the section, subject to the condition of keeping the perimeter unchanged in length, this length being expressed by a complete elliptic integral of the second kind, of which the modulus is the eccentricity of the ellipse. This problem was mentioned by Sir W. Thomson at the British Association in 1888; but we have not yet seen any development of it published by him.

Mr. Worthington, on the other hand, treats the question from the point of view of pure stretching; and now, with rectangular cross-section of the tube, as he supposes, a thrust in the inner wall due to the internal pressure will cause this wall to contract, while the pull in the outer wall will cause this wall to elongate; and thus an increase of internal pressure would cause the tube to curl up, the opposite effect to what happens when the bending effect due to the outward bulging of the flat walls is considered the leading phenomenon.

Even with a circular cross-section the stretching hypothesis would prove that the tube curls up under internal pressure; but this effect would be so small as to be imperceptible, because of the enormously greater stresses required for stretching than for bending in a thin tube; and this is found to be practically the case, inasmuch as the circular cross-section of the tube destroys all indications; and further, that the indications of the tube are reversed in direction when the axes of the elliptical cross-section are interchanged so that the minor axis is perpendicular to the plane of the circular axis of the tube.

The action of Bourdon's gauge is a differential effect; the bending of the surface changes the curvature one way, and the stretching produced by the same pressure the other way; but the bending effect is so much greater than that of stretching, that the latter may be left out of account.

In Gunnery we have, in a similar manner, two antagonistic causes producing a tendency for an elongated rifled projectile to deviate from a vertical plane of motion. If fired from a gun rifled with a right-handed screw, the vortex set up in the air by the spinning of the projectile causes differences of pressure, tending to deviate the projectile to the left, and this effect is sometimes very noticeable with golf or tennis balls; but, in addition, the forces set up by the tendency of the projectile to fly with its axis in the tangent of the trajectory urge the projectile to the right, and these latter forces are found to preponderate in practice.

A mathematician might be tempted to apply to the problem of Bourdon's gauge the formulas on the equilibrium of elastic plates and their change of curvature, anticlastic and synclastic, which are given in Thomson and Tait's "Natural Philosophy" (§§ 711–720), but these formulas apply only to a plate originally plane; and, besides, the applied pressures of the liquid complicate the analysis of the question to an extent which has not yet been overcome by elasticians.

The final conclusion would thus appear to be, that any quantitative formula cannot be hoped for yet, for a long time; but that Lord Rayleigh's reasoning, quoted above, gives a clear and concise descriptive explanation of the action.

The analogous practical problem of the resistance of flues to collapse still stands in need of a rational theory, when the supporting influence of the ends or of collapse rings is taken into account. When this question has received satisfactory treatment at the hands of theorists, we may hope to pass on to the far more difficult quantitative theory of Bourdon's gauge.

A. G. GREENHILL.

NOTES.

THE half-yearly general meeting of the Scottish Meteorological Society was held in the hall of the Royal Scottish Society of Arts, Edinburgh, on Monday afternoon. The following papers were read:—Influenza and weather, with special reference to the recent epidemic, by Sir Arthur Mitchell and Dr. Buchan; the temperature of the high and low-level Observatories of Ben Nevis, by T. Omond, Superintendent; thunderstorms at the Ben Nevis Observatory, by R. C. Mossmann. In the last Report presented by the Council, reference was made to a proposed systematic observation of the numbers of dust-particles in the atmosphere with the instrument recently invented by Mr. John Aitken, and an opinion was

expressed that, for many reasons, Ben Nevis Observatory was the place where such observations could be most satisfactorily conducted. From the Report presented on Monday, we learn that a grant of £50 has been obtained from the Government Research Fund for commencing this novel and important investigation. Two instruments, constructed by Mr. White, of Glasgow, under the direction of Mr. Aitken, have been obtained—one to be placed permanently within the Observatory itself, and the other, a portable instrument, for outdoor observation. Both instruments are now at the Observatory, and the regular work of observation has begun. The Report also states that the delay in completing the buildings of the low-level Observatory at Fort William turned out to be more serious than was contemplated. This has arisen from various causes, chiefly from the great drought in the West Highlands last summer rendering it necessary that the ships conveying the stones for the building from Elgin be sent round the north and west coast instead of through the Caledonian Canal, which for the time was closed for through traffic; and also from the wet, broken weather of the past winter. In about three weeks the Observatory will be completed, and immediately thereafter the Meteorological Council will erect the self-registering instruments which were originally at Armagh, and otherwise supply a complete outfit of instruments for a first-class Meteorological Observatory. An additional observer has been engaged, and the staff of the two Observatories now consists of Mr. Omond, superintendent, and three assistants. By arrangement with the Post Office, direct communication will be opened between the two Observatories. The regular work of recording the continuous observations will be begun in May. The Directors of the Ben Nevis Observatory will thus soon be in a position to put scientific men in possession of two sets of hourly observations of the completest description, one at the top and the other at the foot of the mountain. With these observations, the changes of the conditions of the weather may be followed hour by hour; particularly those great changes, so vital and essential to the advancement of our knowledge of storms, which take place in the lowermost stratum of the atmosphere between the two Observatories. It is within this aërial stratum, of a vertical height of 4406 feet, that the gradual development of many weather changes from hour to hour may be satisfactorily investigated.

THE Chemical Society held its first anniversary dinner at the Hôtel Métropole on Thursday evening last. Among those present were the Presidents of the Royal Society, the Institute of Civil Engineers, the Society of Chemical Industry, the Institute of Chemistry, the Pharmaceutical and the Physical Societies, Sir F. Abel, Sir Henry Roscoe, Sir F. Bramwell, Mr. Thiselton-Dyer, Prof. J. Dewar, Dr. J. H. Gladstone, and Mr. W. Crookes. Dr. W. J. Russell, the President, in proposing posperity to the Chemical Society, sketched briefly the history of its rise and development. Sir Frederick Abel gave the toast of "Kindred Societies and Institutions," referring to the far-reaching character of the science of chemistry. There was not, he said, a single society or institution which was not dependent upon chemists for, at any rate, some amount of the usefulness which it exercised. The Royal Society was the great parent of them all; and the Royal Institution demanded special homage on account of the splendid discoveries made under its auspices, so many of which were specially interesting to chemists. Sir G. Stokes, in response, said that though specialism had been gaining ground very widely of late years, and though each branch of science had its own particular exponents enrolled in their own association, yet the old society, with which he had the honour to be closely connected, was not altogether effete. He thought that chemistry had as much need of cognate societies as any other branch of scientific research. Sir Lowthian Bell also replied. Prof. M. Foster, secretary to the Royal Society, proposed "The Visitors," and the toast was responded to by Sir F. Bramwell and by Mr. Thiselton Dyer. The health of the chairman was proposed by Sir H. Roscoe.

ON Friday evening last the learned societies of Newcastle held their second annual gathering at the Durham College of Science. Among the societies represented were the following: the Durham College of Science, Engineering Students' Club, Foremen Engineers and Draughtsmen, Geographical Society, Institute of Mining and Mechanical Engineers, Literary and Philosophical Society, Medical Society, Microscopical Society, Natural History Society, N.E.C. Institution of Engineers and Shipbuilders, Pharmaceutical Association, Photographic Association, Society of Antiquaries, and Society of Chemical Industry. The *Newcastle Daily Journal* says that the professors of the Durham College of Science "worked hard for the success of the gathering," and that "the exhibits which they explained in the chemical, physical, geographical, botanical, and other departments in the building, afforded a vast amount of pleasure."

BY permission of the trustees of the British Museum, the *conversazione* of the Society of Arts will be held this year at the Natural History Museum, South Kensington.

MR. WRAGGE, Government Meteorologist, Queensland, has been dangerously ill with fever caught some time since in his tours of inspection. He has now gone to the Darling Downs to recruit his heath, which has been seriously undermined.

THE following lectures on scientific subjects will probably be delivered at the Friday evening meetings at the Royal Institution after Easter:—Friday, April 18, Sir Frederick Bramwell, F.R.S., welding by electricity; Friday, April 25, Sir John Lubbock, Bart., M.P., F.R.S., the shapes of leaves and cotyledons; Friday, May 9, Mr. R. Brudenell Carter, colour-vision and colour-blindness; Friday, May 16, Prof. Raphael Meldola, F.R.S., the photographic image; Friday, May 23, Prof. A. C. Haddon, manners and customs of the Torres Straits islanders; Friday, May 30, A. A. Common, F.R.S., astronomical telescopes; Friday, June 6, Prof. W. Boyd Dawkins, F.R.S., the search for coal in the South of England.

AT the twenty-first annual meeting of the Norfolk and Norwich Naturalists' Society, held at the Norwich Museum on March 25, Mr. Henry Seebohm was elected president for the ensuing year. The treasurer's report showed that the financial condition of the Society was very satisfactory, and that during the past year there had been an increase of several members. The retiring president, Dr. Taylor, after briefly reviewing the work of the Society during the past year, delivered an address on "Microbes."

THE London Geological Field Class, under the direction of Prof. H. G. Seeley, F.R.S., has made arrangements for a number of excursions, in which many students might find it pleasant and profitable to take part. One set of excursions is specially arranged for the practical study of geography. Others are planned for the illustration of the geological structure of the London district.

A VIOLENT earthquake shock was felt at Trieste on March 26 at 20 minutes past 9 p.m.

AT the last meeting of the Scientific Committee of the Royal Horticultural Society, Mr. Morris alluded to the peculiar vegetation of St. Helena, now confined, for the most part, to a small area in the central and higher part of the island. Many of the trees formerly native to the island are now all but, or quite, extinct. Among them is a species of Trochetia, or Melhania. The trunks of this tree are embedded in the cliffs of the island, and are dug out by the inhabitants for the sake of manufacturing ornaments. The following quotation from Melliss's

exhaustive work on St. Helena refers to this plant:—"The Native Ebony of St. Helena.—This plant I believe to be now extinct. It formerly grew on the outer portions of the island, near the coast, at altitudes of 2 to 4, where the weather-beaten stems are still found deeply embedded in the surface-soil. The last plant I saw was a small one growing in the garden at Oakbank, about twenty-five years ago, but it is not there now, and I have searched the whole island over for another, but in vain. The leaves were dark green, and the flowers white; the wood is very hard, heavy, black in colour, and extremely brittle. It is still collected and turned into ornaments, which are much prized on account of its rarity. That this tree once formed a considerable portion of the vegetation clothing the island on those parts that are now quite barren, is strongly evidenced by the many references to it in the local records. Pl. 29. It is the *Dombeya erythroxylon* of Andr., *Bot. Repos.*, vi., t. 389, not of Willdenow." It is interesting to know that the plant is still in existence under cultivation at Kew (and perhaps elsewhere), under the name of *Dombeya erythroxylon*. At the present time the plant, which was obtained from the gardens at Herrhausen, is in flower at Kew. Mr. McLachlan called attention to the interesting remark on the rare plants of St. Helena, contained in Mr. Wollaston's book on the Coleoptera of the Atlantic islands.

CAPT. DELPORTE, Professor of Topography, Astronomy, and Geodesy, at the Military School of Brussels, has just started for the River Congo, for the purpose of making geodetic researches.

THE Geographical Society of Berlin has presented the sum of 1000 marks (£50), to Dr. Hettner for a journey of research in the southern provinces of Brazil.

SOME prehistoric German tombs were recently excavated on the road leading from Apolda to Jena. About 20 skeletons were found (two being without skulls), and a number of ornaments and weapons.

IN the course of some excavations lately made at Ludwigshafen, on the Rhine, the tibia and two teeth of a mammoth, and the jaw of a stag, were found. The skeleton of another "antediluvian" animal was discovered in the limestone near Oberhildesheim. The researches are being continued.

THE *Zoologist* for 1884 announced a proposed supplement to Thompson's "Natural History of Ireland," and contributions of information were invited from persons interested in the subject. A considerable amount of fresh material has been accumulated, but as it relates chiefly to birds, it is now intended that the supplement shall deal only with ornithology. The new work will be published by Messrs. Gurney and Jackson, and an appeal for additional facts has been issued to students who may be able and willing to supply notes. Anyone who is in a position to respond to this appeal is requested to communicate with Mr. R. J. Usher, Cappah, Lismore, Ireland.

MR. ELLIOT STOCK has issued the seventh edition of "Days and Hours in a Garden," by E. V. B. The volume is prettily printed and bound, and lovers of the country will find much to interest them in the writer's bright and pleasant descriptions.

THE Royal University of Ireland has issued its Calendar for the year 1890, and a supplement consisting of the examination papers of 1889.

THE first edition of the life of the Rev. J. G. Wood, by his son, the Rev. Theodore Wood, has been already exhausted; and a second edition is about to be issued.

A FACT noted by Mr. T. H. Hall in the new number of the *Entomologist's Monthly Magazine* indicates the extraordinary variety of conditions in which beetles may thrive. The men employed in breaking up an old disused gasometer at Home Park Mills, King's Langley, spoke to him of some "very curious beetles," which were living in the rusty water at the bottom of the hole left when the iron casing had been removed. Both the water and mud were strongly impregnated with gas. The beetles proved to be of the *D. marginalis* species, and were there in some numbers. Many were carried away when the water was pumped off, but Mr. Hall secured specimens from the mud and shallow water left. He says:—"They carry with them a strong odour of gas, even after two or three fresh-water baths, and the grooves in the elytra of the females are filled with a ferruginous mud which is difficult to remove. In other respects they appear to be quite normal in form and colour. I think this old gas-holder must have been their home for a long period of beetle life, judging from the time of year when they were found, a fortnight ago, and from the number of *both* sexes seen. The water was partly enclosed and quite stagnant, being unconnected with any other water. Were they there by choice? If not, why did they not emigrate? Most likely they came there by chance, as they are plentiful in the canal not far away, and lacking the inclination to depart, 'made themselves at home.' Had the water been disagreeable to them, we may presume they would not have done so; they were quite active when disturbed."

ACCORDING to a French journal, the number of foreign students now studying in Paris is about 1000, of whom 729 (107 of them women) are studying medicine, and 182 law. Literature has 66 (including 9 women), science 60, and pharmacy 23. It is remarkable that Russia furnishes the largest contingent of the foreign medical students, viz. 150, America coming next with 139. We find no mention of England. The foreign element is, on the above estimate, about one-tenth of the whole.

THE Punjab Forest Administration Report for 1888–89 was recently published. During the year, nine thousand acres were added to the area of gazetted forests in the Multan district. This area was taken up in pursuance of the policy of establishing irrigated plantations in connection with several new canals constructed in what are known as the "Bar" tracts—that is, the dry upland deserts of the Punjab. The number of forest fires increased during the year, and 17,617 acres were burnt as against 10,324 during 1888. The financial results are satisfactory. The net revenue amounted to Rs. 4,52,846, or nearly half a lakh in excess of the net revenue of the preceding year. The Conservator complains that the Working Plans Branch cannot get on with their work on account of the undermanning of the Department. As a consequence, working plans are only in force over 364 square miles, out of a total of two thousand square miles gazetted and six thousand controlled by the Forest Department. Experiments with exotics were made, but the result was not encouraging. European fruit-trees have been introduced in many places with great success.

THE first Report published by the Marine Fisheries Society of Great Grimsby is a modest record of work done and investigations decided on by an institution which, by employing scientific methods, will probably amass information of great value to the biologist, and improve our fisheries in their commercial aspects. The Society was incorporated in June 1888. It has already established an aquarium and hatchery which is 37 feet by 21 feet, and a small museum and library. The building has a frontage of 50 feet, and is situated at Cleethorpes, facing the Promenade, two miles distant from Grimsby. The tanks are set on concrete walls; they were purchased from the National Fish-Culture Association, and originally formed the aquarium at the Fisheries Exhibition at South Kensington. They form a reservoir storing 4000 gallons of sea-water, from which the water is

pumped into a wooden tank 10 feet above the hatchery, holding 1200 gallons. Thus a constant circulation of the water in the tanks is maintained. The water is pumped from the sea at high water, and left to settle some days in a storage reservoir before use; each hatching tank has room for twelve wooden trays, measuring 16 inches by 10 inches, by 9 inches in depth, with a canvas strainer at the bottom to prevent the eggs escaping. The Society aims at recording observations respecting marine life, and the improvement of the fisheries of the United Kingdom, by the artificial propagation of marine fishes and Crustacea, by the pursuit of scientific observations and investigations respecting the natural history, habitat, migration, spawning food, and the effect of weather, temperature, and conditions of the water, currents, tides, light, and darkness upon the fauna of the sea; by the protection of young fish, and the introduction of practical appliances for the capture of mature fish; by endeavouring to ascertain the best methods of transporting fish in a fresh condition, and economically preserving them. By admitting fishermen into the Society, at a nominal subscription, they hope to get numerous observers and collectors from amongst those who spend their life reaping the harvest of the sea.

AT the last meeting of the Société Chimique de Paris a paper by M. Meslans was presented by M. Moissan, announcing the isolation of fluoroform, CHF_3, the fluorine analogue of chloroform, $CHCl_3$. A brief abstract of this preliminary communication will be found in the *Chemiker Zeitung* for March 26. During the course of the work recently published concerning propyl and isopropyl fluorides, M. Meslans had occasion to study the action of silver fluoride upon iodoform. The result of this action was found to vary according to the conditions of experiment, liquid products being obtained under certain conditions, and gaseous products under others. The end result, however, was always the production of a gas, which turns out to be fluoroform. Chloroform, as is well known, is readily attacked by a warm alcoholic solution of potash, potassium chloride and potassium formate being produced: $CHCl_3 + 4KOH = H.COOK + 3KCl + 2H_2O$. It is interesting to learn that fluoroform behaves in precisely the same manner, for the gas is decomposed by either aqueous or alcoholic potash with formation of fluoride and formate of potassium. On being heated to redness in a glass tube fluoroform is also decomposed, with production of gaseous silicon tetrafluoride and a deposit of carbon. The gas is only very slightly absorbed by water, but it dissolves readily in chloroform or alcohol. Fluoroform has also been prepared by substituting chloroform or bromoform for the iodoform used in the first experiments.

AT the same meeting M. Chabrié reported that he also had obtained a gas by heating silver fluoride with chloroform in a sealed tube, which yielded potassium formate with potash, and was evidently identical with the fluoroform described by M. Meslans. The density of the gas was determined, and found to be 2·414. Fluoroform possesses the density 2·43, so there can be no doubt as to the identity of the gas. Although so readily attacked by warm potash, it was found that a cold alcoholic solution of potash was almost incapable of acting upon it.

M. MOISSAN also presented another interesting paper in the names of MM. Guenez and Meslans, describing the isolation of fluoral, $CF_3.CHO$, the analogue of chloral, $CCl_3.CHO$, the tri-chlor derivative of common aldehyde, $CH_3.CHO$, and the hydrate of which has recently become so famous as a drug. Fluoral, like fluoroform, is a gas, and has been obtained by heating silver fluoride with anhydrous chloral. The gas dissolves to only a very slight extent in water, but is absorbed by aqueous or alcoholic potash with formation of formate and fluoride of potassium, thus again resembling its chlorine analogue. To complete the proof of its identity, the density of the gas was determined and found to agree very closely with the calculated density of anhydrous fluoral.

THE additions to the Zoological Society's Gardens during the past week include two Ring-necked Pheasants (*Phasianus torquatus* ♂ ♀), British, presented by H.R.H. the Prince of Wales, K.G.; a Chacma Baboon (*Cynocephalus porcarius* ♀) from South Africa, two Indian Pythons (*Python molurus*) from India, five Common Boas (*Boa constrictor*) from South America deposited; three Red-footed Ground Squirrels (*Xerus erythropus*) from West Africa, two Himalayan Monauls (*Lophophorus impeyanus* ♀ ♀) from the Himalayas, two Diuca Finches (*Diuca grisea*), a Black-chinned Siskin (*Chrysomitris barbata*) two Field Saffron Finches (*Sycalis arvensis*), an Alaudine Finch (*Phrygilus alaudinus*) from Chili, purchased; a Hog Deer (*Cervus porcinus* ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBJECTS FOR THE SPECTROSCOPE.

Sidereal Time at Greenwich at 10 p.m. on April 3 = 10h. 48m. 43s.

Name.	Mag.	Colour.	R A. 1890.	Decl. 1890.
			h. m. s.	° ′

(3) 58 Leonis	4·5	Whitish-yellow.	10 54 54	+ 4 13
(4) θ Leonis...	3	White.	11 8 30	+16 2
(5) 145 Schj.	8	Red.	12 19 36	+ 1 23
(6) S Coronæ	Var.	Reddish-yellow.	15 16 55	+31 46

Remarks.

(1) This is the well-known nebula 97 M, near β Ursæ Majoris. In the General Catalogue it is described as "a planetary nebula, very bright, very large, round; at first very gradually, then very suddenly brighter in the middle to a planetary disk; 19·0s. in diameter." Lord Rosse's drawing of the nebula indicates a very complex structure. I examined the nebula recently with Prof. Lockyer's 30-inch reflector at Westgate-on-Sea, but was unable to see all the details shown in Lord Rosse's drawing. The nebula appeared to be a large disk, ill-defined at the edges, and equally illuminated, with the exception of two darker disks situated diametrically opposite to each other, each being about half a radius in diameter. Dr. Huggins observed the spectrum in 1866, and found it to consist of bright lines. The two lines near λλ 500 and 495, and possibly a little continuous spectrum were recorded. On the occasion above referred to I saw the three usual nebula lines and the hydrogen line at G, but was unable to continue the observations on account of clouds. In further observations, additional lines ought to be looked for, and the character of the chief line near λ 500 particularly noted, as in the case of the nebula G.C. 2102, given last week.

(2) A star of Group II. Dunér states that the bands 2-8 are well seen, but that they are not strongly marked. It is important to secure further observations of stars like this, as there may very well be other differences besides the weakening of the bands as compared with those in which the banded spectrum is more fully developed.

(3) This has a fine spectrum of the solar type (Vogel). The usual differential observations are required.

(4) The spectrum of this star is a typical one of Group IV. (Vogel). The hydrogen lines are probably therefore very thick, and the metallic lines very thin, if visible at all. The thicker the hydrogen line the hotter the star, and the higher therefore its place on the "temperature curve."

(5) Vogel and Dunér agree in describing the spectrum of this star as a very fine one of Group VI. The three carbon bands are stated to be visible, but the intensity of the band near λ 564 relatively to the others is not given. This point should therefore receive attention. The secondary bands 4 and 5, and possibly 2 and 3 are visible. It is interesting to note that this star shows considerably more detail than several brighter ones of the same group.

(6) This variable will reach a maximum about April 9. Its period is about 360 days, and the magnitudes at maximum and minimum are 6·1–7·8 and 11·9–12·5 respectively (Gore). The spectrum is a very fine one of Group II., and the great range of variation makes it extremely probably that bright lines will appear at maximum or soon after, as already observed by Mr. Espin in variables with similar spectra. Variations in the intensities of the bright carbon flutings should also be noted.

A. FOWLER.

THE GREAT COMET OF 1882.—The *Bulletin Astronomique* for February 1890 reproduces with some additions a paper presented by M. F. Tisserand to the Academy of Sciences on February 3. It will be remembered that the segmentation of the nucleus of this comet was observed on September 30, 1882—that is, thirteen days after perihelion passage, and that Mr. Common in January 1883 saw five nuclei in a line. From an elaborate investigation into the conditions necessary for the development of these secondary nuclei, M. Tisserand concludes that the cause existed in the comet itself, and was not the result of external influence. The minimum relative variation required for the disaggregation of the nucleus is $\frac{1}{8000000}$ of the perihelion velocity. And it is suggested that this variation may be produced by interior actions, collisions, mutual attractions, or explosions, because of an excessive increase of temperature or the rotation of the head.

MELBOURNE STAR CATALOGUE.—In 1874 the First Melbourne General Catalogue of 1227 stars for the epoch 1870 was issued. The Second General Catalogue has just been received, and contains 1211 stars for the epoch 1880, deduced from observations made at the Melbourne Observatory under the direction of Mr. Ellery from 1871·0 to 1884·7. The separate results and the details of the observations from which this Catalogue has been compiled are contained in vols. v., vi., and vii., of the *Melbourne Observations*, and in the present Catalogue explanations are given of the processes used in forming the stars' places and the corrections applied. The whole of the observations were reduced and prepared for publication by Mr. E. J. White, the First Assistant Astronomer.

COMET *a* 1890.—The first comet of this year was discovered just before sunrise on March 19 by Mr. Brooks, of Geneva, U.S. Its exact place was found to be—

Cambridge Mean Time.	R.A.	Decl.
	h. m. s.	° ′ ″
21 March ... 16h 57·5m	21 9 34·07	6 25 30 N.

The daily movement in right ascension is + 16s., and in declination + 25′.

DISCOVERY OF ASTEROIDS.—On March 20, Dr. Palisa, at Vienna, discovered another minor planet, and the telegram announcing his discovery was received at the *Astronomische Nachrichten* office at midday on March 21. This comet is of interest, for, from its rapid movement, viz. – 25′ in R.A. and + 10′ in N.P.D., it appears to be near to the earth.

M. Charlois, of Nice Observatory, discovered a minor planet on March 10, and re-observed it on March 20. This brings the number of asteroids up to 290.

The asteroid (284) discovered by Prof. Luther on February 24 has received the name of Glauke.

SOLAR ACTIVITY IN 1889.—The record of the past year as to solar phenomena presents several noteworthy features. (1) The number of days on which the sun appeared to be free from either spots or faculæ; the days without spots being 211 as compared with 158 in 1888; and the days when neither spots nor faculæ were seen being more than twice as numerous last year as in the year previous. (2) The distinct but temporary revival of spot activity during the months of June, July, August, and September. (3) The appearance of spots in high latitudes; and lastly, the remarkable falling off in chromospheric phenomena, particularly during the last months of the year. It is, therefore, still difficult to be certain whether we have yet reached the actual minimum or no; the revival of the spots during last summer, connected as it was with so remarkable an increase in their mean distance from the equator, seemed to point to the minimum having been passed; but the season of almost perfect quiet which followed it, together with the decrease in the number and size of the prominences, favour the opposite conclusion. The mean daily spotted area for 1889 was less than that for 1888, but only by about one-seventh.

The three most remarkable groups of 1889 were those first seen on June 16, June 29, and August 2 respectively. The first-named was the largest group of the year; it formed and disappeared on the further side of the sun, and was seen during three rotations. The third was also seen during three rotations, but formed and died out in the visible hemisphere. It was the second group as to dimensions, and lay in S. lat. 20°, whilst the spot of June 16 was in S. lat. 6°. The spot of June 29 was only a very small one, and lasted but a couple of days, but was noticeable from its high latitude, 40° S. A fourth group, that first seen on August 9, though not attaining so large a mean area as the spot of June 16, exceeded it on one particular day, August 15.

The following table gives the monthly numbers for spots and faculæ as supplied by Prof. Tacchini in the *Comptes rendus*, vol. cviii. No. 21, vol. cix. No. 4, and vol. cx. No. 5, and may be compared with those given in NATURE for 1889 March 7, and in previous volumes:—

1889.	Proportion of days without spots.	Sun-spots. Relative frequence.	Relative size.	Mean daily number of groups.	Faculæ. Relative size.
January	1·00	0·00	0·00	0·00	6·00
February	0·50	3·26	8·12	0·56	1·56
March	0·62	1·69	3·64	0·50	6·81
April	0·60	0·65	4·35	0·40	7·25
May	0·96	0·04	0·65	0·04	5·30
June	0·56	1·97	25·22	0·45	9·63
July	0·39	2·75	16·97	0·87	14·35
August	0·19	6·97	20·03	1·26	17·77
September	0·48	1·18	8·22	0·61	28·48
October	0·73	0·64	1·55	0·27	18·18
November	1·00	0·00	0·00	0·00	0·62
December	0·61	1·68	4·09	0·65	29·55

The table shows that as in 1888 the faculæ did not vary quite in accordance with the spots, September and December being heavy months for the former, their relative area then exceeding that for any month since July 1886. The prominences on the other hand showed a very marked falling off towards the end of the year; February and March, light months for spots and faculæ, being much the most prolific as to the flames. The following are the mean numbers for the prominences resulting from Prof. Tacchini's monthly reports. It must be borne in mind that the difference in the atmospheric conditions of England and Italy renders it impossible to compare Prof. Tacchini's results with those formerly given by the late Rev. S. J. Perry, and which have been incorporated in former annual summaries in NATURE.

Prominences.

	Days of observation.	Mean daily number.	Mean height. ″	Mean extent. °
1887	214	8·26	45·2	1·7
1888	227	7·94	45·9	1·5
1889	247	3·20	34·7	1·1

The variations in the magnetic elements accorded in their more general features, though not in details, with those of the sunspots, as the following table given by Dr. R. Wolf in the *Comptes rendus*, vol. cx. No. 3, sufficiently shows:—

1889.	Wolf's relative numbers (Zurich). r	Δr	Variation in magnetic declination (Milan). r	Δr
January	1·0	– 12·0	1·75	– 1·28
February	7·9	+ 0·9	3·99	+ 0·97
March	6·3	+ 0·0	6·17	– 0·94
April	4·9	+ 1·0	8·85	+ 0·58
May	2·4	– 8·4	8·19	– 0·29
June	7·0	+ 0·5	8·86	– 0·41
July	8·0	+ 6·1	8·25	– 0·32
August	20·6	+ 18·7	8·99	– 0·18
September	6·3	– 1·5	6·84	– 0·47
October	0·0	– 2·0	6·10	– 0·22
November	0·0	– 12·9	2·55	+ 0·37
December	5·7	– 4·2	1·96	+ 0·20
Mean	5·8	– 0·9	6·04	– 0·17

Dr. Wolf's formula for Milan, $v = 5'.62 + 0.045\ r$, with $r = 5.8$, would give $v = 5'.88$, a much closer accord than for the two preceding years.

THE GLOW OF PHOSPHORUS.[1]

THE word *phosphorus*, originally applied to any substance, solid or liquid, which had the property of shining in the dark, has gradually lost its generic sense, and is nowadays practically restricted, as a designation, to the wax-like inflammable substance which plays such an important part in the composition of an ordinary lucifer match. Phosphorus, indeed, is one of the most remarkable of the many remarkable substances known to the chemist. The curious method of its discovery, the universality of its distribution, its intimate connection with the phenomena of animal and vegetable life, its extraordinary physical properties and chemical activity, its abnormal molecular constitution, the Protean ease of its allotropic transformations—all combine to make up a history which abundantly justifies its old appellation of *phosphorus mirabilis*. Godfrey Hankewitz more than 150 years ago wrote: "This phosphorus is a subject that occupies much the thoughts and fancies of some alchymists who work on microcosmical substances, and out of it they promise themselves golden mountains." Certainly no man of his time made more in the way of gold out of phosphorus than Mr. Hankewitz, for at his little shop in the Strand he enjoyed for many years the monopoly of its sale, guarding his *Arcana* with all the jealousy of a modern manufacturer of the element.

Phosphorus, or, as it was then called, the *noctiluca*, was first seen in this country in 1677. It was shown to Robert Boyle, who had already worked on phosphorescence in general, and who seems to have been specially struck with the remarkable peculiarity of a factitious body which could be made "to shine in the dark without having been befo e illumined by any lucid substance and without being hot as to sense." In these respects the substance differed from all the *phosphori* hitherto known. The conditions which determine its glow were the subject of the earliest observations on phosphorus, and Boyle has left us a minute account of his work on the point. In the first place, he noticed that the substance was only luminous in presence of air. He accurately describes the nature of the light, and noticed that the water in which the phosphorus was partially immersed acquired "a strong and penetrant taste, . . . and relished a little like vitriol." On evaporation it would not "shoot into crystals, . . . but coagulated into a substance like a Gelly, or the Whites of Eggs which would be easily melted by heat." On heating this "Gelly" it gave off "flashes of fire and light," and had a "garlick smell." He also found that the *noctiluca* was soluble in certain oils, and he particularly mentions oil of cloves as a convenient means of showing the luminosity, as it is "rendered more acceptable to the standers-by by its grateful smell." "In Oyl of Mace it did not appear luminous nor in Oyl of Aniseeds." Boyle describes a number of experiments showing how small a quantity of the phosphorus is required to produce a luminous effect. "A grain of the *noctiluca* dissolved in Alkohol of Wine and shaken in Water; it render'd 400,000 times its weight luminous throughout. And at another Tryal I found that it impregnated 500,000 times its weight; which was more than one part of Cochineel could communicate its colour to." "And one thing further observable was that when it had been a long time exposed to the air it emitted strong and odorous Exhalations distinct from the visible Fumes." The strong and odorous exhalations we now know to be ozone.

The earlier volumes of the Philosophical Transactions contain several papers on the luminosity of phosphorus, and one by Dr. Frederic Slare is noteworthy as giving one of the earliest, if not actually the earliest account of what is one of the most paradoxical phenomena connected with the luminosity of phosphorus, namely its increase on rarefying the air. "It being now generally agreed that the fire and flame [of phosphorus] have their pabulum out of the air, I was willing to try this matter *in vacuo*. To effect this, I placed a considerable lump of this matter (phosphorus) under a glass which I fixed to an engine for exhausting the air; then presently working the engine, I found it grow lighter [*i.e.* more luminous] though a charcoal that was well kindled would be quite extinguished at the first exhaustion; and upon the third or fourth draught which very well exhausted the glass, it much increased its light, and continued so to shine with its increased light for a long time; on re-admitting the air, it returns again to its former dulness." This observation was repeated and its result confirmed by Hawksbee in this country and by Homberg in France, and seems subsequently to have led Berzelius, and after him Marchand, to the conclusion that the luminosity of phosphorus was altogether independent of the air (*i.e.* the oxygen) but was solely due to the volatility of the body. Many facts, however, combine to show that the air (oxygen) is necessary to the phenomenon. Lampadius found that phosphorus would not glow in the Torricellian vacuum; and Lavoisier, in 1777, showed that it would not inflame under the same conditions; and the subsequent experiments of Schrötter, Meissner, and Müller are decisive on the point that the glow is the concomitant of a chemical process dependent upon the presence of oxygen. It is, however, remarkable that phosphorus will not glow in oxygen at the ordinary atmospheric pressure and temperature, but that if the oxygen be rarefied the glow at once begins, but ceases again immediately the oxygen is compressed. Indeed, phosphorus will not glow in compressed air, and the flame of feebly burning phosphorus may be extinguished by suddenly increasing the pressure of the gas. Phosphorus, however, can be made to glow in oxygen at the ordinary pressure or in compressed air if the gases be gently warmed. In the case of oxygen the glow begins at 25° and becomes very bright at 36°. In compressed air the temperature at which the glow is initiated depends upon the tension. If the oxygen be absolutely deprived of moisture the phosphorus refuses to glow under any conditions. This fact, strange as it may seem, is not without analogy; the presence of traces of moisture appears to be necessary for the initiation or continuance of chemical combination in a number of instances.

It was observed by Boyle that a minute quantity of the vapour of a number of essential oils extinguished the glow of phosphorus. The late Prof. Graham confirmed and extended these observations; he showed that relatively small quantities of olefiant gas and of the vapours of ether, naphtha, and oil of turpentine entirely prevented the glow; and subsequent observers have found that many essential oils, such as those of peppermint and lemon and the vapours of camphor and asafœtida, even when present in very small quantity, stop the absorption of oxygen and the slow combustion of phosphorus in air.

It has been established that whenever phosphorus glows in air or in rarefied oxygen, ozone and hydrogen peroxide are formed, but it is not definitely known whether the formation of these substances is the cause or the effect of the chemical process of which the glow is the visible sign. That there is some intimate connection between the luminosity of the phosphorus and the production of these bodies is highly probable. Schönbein, as far back as 1848, sought to demonstrate that the glow depends on the presence of ozone. It is certainly true that many of the substances, such as the essential oils, which prevent the glow of phosphorus, also destroy ozone. At a low temperature, phosphorus produces no ozone in contact with air, neither does it glow. It has been found, in fact, that, with air, ozone is produced in largest quantity at 25°, at which temperature phosphorus glows brightly. On the assumption that the oxidation of the phosphorus consists in the immediate formation of the highest oxide, the production of the ozone and the hydrogen peroxide has been represented by the following equations:—

$$P_2 + 3O_2 = P_2O_5 + O.$$
$$O + O_2 = O_3.$$
$$O + H_2O = H_2O_2.$$

Both these reactions may, of course, go on simultaneously; ozone and hydrogen peroxide are not mutually incompatible; the synthesis of hydrogen peroxide by the direct oxidation of water seems to occur in a number of processes. But such symbolic expressions can at most be only very partial representations of what actually occurs. It is highly probable that the combination which gives rise to the glow only occurs between the *vapour* of phosphorus and the oxygen. Phosphorus is sensibly volatile at ordinary temperatures, and by rarefying the atmosphere in which it is placed its volatilization is increased, which serves to account for the increased glow when the pressure of the gas is diminished. When phosphorus is placed in an atmosphere of hydrogen, nitrogen, or carbonic acid, these gases, when brought into contact with oxygen, become luminous from the oxidation of the vapour of phosphorus diffused through them. The rapidity of volatilization varies with the particular gas; it is greatest in the case of hydrogen, and least in that of carbonic acid. Indeed, a stream of hydrogen gas at ordinary temperatures carries away comparatively large quantities of phosphorus, which may be collected by appropriate solvents. No ozone and no glow is

[1] Lecture delivered on Friday evening, March 14, at the Royal Institution, by Prof. Thorpe, F.R.S.

produced in oxygen gas at ordinary temperatures and pressures, but on warming the oxygen, both the ozone and the glow are formed. On passing ozone into oxygen at temperatures at which phosphorus refuses to glow, the phosphorus at once becomes luminous, oxygen is absorbed, and the characteristic cloud of oxide is produced, and the effect continues so long as the supply of ozone is maintained. A drop of ether at once extinguishes the glow. The ether is in all probability converted into vinyl alcohol with simultaneous formation of hydrogen peroxide by the reaction indicated by Poleck and Thümmel:—

$$\left.\begin{matrix}CH_3CH_2\\CH_3CH_2\end{matrix}\right\rangle O + \overset{\bullet}{O_3} = \begin{matrix}CH_2CHOH\\CH_2CHOH\end{matrix} + \left.\begin{matrix}HO\\HO\end{matrix}\right\}.$$

A. W. Wright has shown that formic, acetic, and oxalic acids are also formed by the action of ozonized oxygen on ether.

Phosphorus combines with oxygen in several proportions, and the study of the mode of formation and properties of these oxides is calculated to throw light upon the nature of the chemical process which attends the glow of phosphorus. Certain of these oxides have recently been the subject of a considerable amount of study in the chemical laboratories of the Normal School of Science. When phosphorus is slowly burned in air, there is produced a considerable quantity of a volatile substance, having a characteristic garlic-like smell, which solidifies, when cooled, in beautiful arborescent masses of white crystals. It melts at about 23°, and boils at 173°. In a sealed tube kept in the dark, it may be preserved unchanged, but on exposure to light, and especially to bright sunshine, it rapidly becomes deep red. It slowly absorbs oxygen at the ordinary temperature and pressure, but from the mode in which the solid product of the reaction (P_2O_5) is deposited, it is evident that the union only takes place between the *vapour* of the oxide and the oxygen gas. Under diminished pressure the act of combination is attended with a glow which increases in brilliancy if ozone be present. On compressing the oxygen, the glow ceases. No ozone is formed during the act of oxidation. The degree of rarefaction needed to initiate the glow depends upon the temperature of the oxide—the warmer the oxide the less is the diminution of pressure required. By gradually warming the oxide, the luminosity steadily increases both in area and intensity, until at a certain temperature the mass ignites. The change from glow to actual flame is perfectly regular and gradual, and is unattended with any sudden increase in brilliancy. In this respect the process of oxidation is analogous to the slow and barely visible burning of fire-damp which is sometimes seen to occur in the Davy lamp, or to the slow combustion of ether and other vapours, which has been specially studied by Dr. Perkin. Other instances of what may be called *degraded combustion* are known to chemists. Thrown into warm oxygen, the substance bursts into flame at once and burns brilliantly, and it also takes fire in contact with chlorine. Alcohol also ignites it, and when it is warmed with a solution of potash or with water it evolves spontaneously inflammable phosphoretted hydrogen. In contact with cold water it suffers only a very gradual change, and many days may elapse before even a comparatively small quantity is dissolved. This substance has long been known; it was discovered, in fact, by the French chemist Sage, but its true nature has only now been determined. Its chemical formula is found to be P_4O_6; hence its composition is similar to that of its chemical analogue, arsenious oxide.
